Vital functions in neurons and astrocytes requiring cellular work are as follows: (a) the glutamate/GABA–glutamine cycle; (b) vesicularization, docking, and exocytosis of neurotransmitters from vesicles; (c) the transmembrane ATPases in both types of cells; (d) actin-filament growth in dendrites; (e) phospholipid and glycolipid metabolism; and (f) axoplasmic transport. The isolated nerve-ending particle (i.e., synaptosome) preparation has been used successfully to study many principles of the metabolic pathways in the brain (Riera et al. 2008). It has been recently demonstrated that in spite of the complexity, metabolism shows certain level of homogeneities across cortical networks of the human brain (Hyder et al. 2013a).

Abbreviations: *Glc*, glucose; *GLUT*, glucose transporter; *HK*, hexokinase; *PGI*, phosphoglucose isomerase; *F6P*, β -D-fructose 6-phosphate; *G6P*, α -D-glucose 6-phosphate; *PFK-1*, phosphofructokinase-1; *FI,6BP*, β -D-fructose 1,6-bisphosphate; *GADP*, D-glyceraldehyde 3-phosphate; *PGK*, phosphoglycerate kinase; *PEP*, phosphoenolpyruvate; *PK*, pyruvate kinase; *MCT*, monocarboxylate transporter; *LDH*, lactate dehydrogenase; *PDH*, pyruvate dehydrogenase; *CS*, citrate synthase;

α -KG, α -Ketoglutarate; *SDH*, succinate dehydrogenase; *OAA*, oxaloacetate; *GDH*, glutamate dehydrogenase; *GLT*, glutamate transporter; *AAT*, aspartate aminotransferase; *PAG*, phosphate-activated glutaminase; *GAD*, glutamate decarboxylase.

Postsynaptic and Action Potentials

Neurotransmitters (e.g., Glu, GABA) released into the synaptic cleft in the course of presynaptic neuronal activity will freely diffuse towards neuronal postsynaptic buttons and nearby astrocytic processes. They will cause either excitatory (EPSP) or inhibitory (IPSP) postsynaptic potentials by receptor-specific flows of ions in the postsynaptic neurons. After the genesis of EPSP/IPSP, ionic gradients are reestablished by way of transmembrane ATPases, which consume large amounts of ATP. Action potentials are generated as a consequence of the spatiotemporal integration of these postsynaptic potentials, and they propagate along nerves. The genesis and propagation of these action potentials cause also the breakdown of the ionic balances across cellular membranes and, therefore, require the use of ATP. In the postsynaptic buttons and axons, the required ATP is produced from Pyr through the TCA cycle and electron-transport/oxidative-phosphorylation pathways.

The Glycolytic Pathway

The glycolytic pathway involves breakdown of Glc into Pyr. Glc is continuously delivered from capillaries to the extracellular milieu through GLUT-1. Cells take up extracellular Glc through GLUT-1 (astrocytes) and GLUT-3 (neurons). In different proportions, Pyr and ATP are produced from glycolysis in both cell types. Breakdown steps at different levels can be either impeded or hastened through the activity of many enzymes in this pathway, which constitute checkpoints located in different cellular compartments. The preparatory phase comprises four steps: the first phosphorylation of Glc by enzyme HK (control point G-1), an isomerase reaction of G6P by enzyme PGI, a phosphorylation of F6P by enzyme PFK-1 (control point G-2), and an aldol reaction

on F1,6BP by enzyme ALDO that finally produces DHAP and GADP. DHAP and GADP are rapidly and reversibly interconverted by TPI, a step essential to produce energy efficiently. The payoff phase comprises five steps: a redox reaction on GADP by enzyme GAPDH to form 1,3BPG, a product with high phosphoryl-transfer potential; a substrate-level phosphorylation of 1,3BPG by enzyme PGK (it is the break-even point in glycolysis); a mutase reaction on 3PG by enzyme PGAM, a hydration of 2PG by enzyme ENO; and a substrate-level phosphorylation of PEP by enzyme PK (control point G-3) to produce Pyr and ATP. There are no transmembrane transporters for G6P; thus, Glc cannot leak out of the cells after it is phosphorylated by HK.

The Glycogen-Shunt Proposition

G6P could have two fates, either being converted into F6P by PGI, and thus continuing along the glycolytic pathway, or otherwise being stored as glycogen polymer. Glycogen polymers are considered as one of the largest energy reservoirs in the brain and could be used as an emergency fuel supply during severe energetic stress resulting not only from a pathological condition (e.g., hypoglycemia, cerebral ischemia) but also from high neuronal activity in a healthy brain. Glycogen polymer breakdown preferentially occurs in the astrocytic compartment, but its activation would plausibly seem to be linked to the neuronal compartment. The OGI may be an important link mediating the balance between the glycolytic pathway and glycogen shunt.

The Astrocyte–Neuron Lactate Shuttle

A fraction of around 15% of the Glc oxidized in neurons is not coupled to the total glutamate–glutamine cycle (Hyder et al. 2006). This fraction might represent ATP needed for non-cycling activities. Based on these observations, it has been suggested that the glutamate–glutamine cycle, a two ATP-consuming dual task (i.e., one ATP is used to convert glutamate into glutamine by glutamine synthetase and the other to reestablish the Na⁺ gradient by the activation of the Na⁺/K⁺ -ATPase), might trigger lactate

production by glycolysis in the astrocytes during the course of neuronal activity, so stimulating them to take up extracellular Glc (Pellerin and Magistretti 2004). Lactate so produced may be released for oxidation in adjacent neurons. It is not at all clear where the oxidation of lactate derived from Glc and/or glycogen metabolism may occur (Hertz et al. 2007). Moreover, during activation, glutamatergic activity in neurons seems better preserved by Glc metabolism than by lactate metabolism. The observed increase of lactate under steady-state sensory stimulation has been explained on the basis of stimulation evoked glycolysis and glycogen-shunt pathways (Shulman et al. 2001a, b). Lactate may be taken up into neurons through the monocarboxylate transporter MCT-2, which has the highest affinity for its substrate. An extensive overproduction of lactate must efflux into the circulating blood. In summary, the astrocyte–neuron lactate shuttle may be facilitated by the differential presence of LDH-1 and LDH-1&5 in neurons and astrocytes, respectively. This shuttle may be favored by the existence of monocarboxylate transporters MCT-2 and MCT-1&4 in neurons and astrocytes, respectively.

TCA Cycle and Oxidative Phosphorylation

The majority of ATPs yielded from Glc oxidation are generated by breakdown of carbon skeletons in the TCA cycle and electron donors located inside the mitochondria. The biochemical mechanisms underlying these energy substrates as well as major enzymatic checkpoints inside the TCA cycle and electron-transport/oxidative-phosphorylation pathway are detailed below. The PDH complex performs the decarboxylation of Pyr by enzymes pyruvate dehydrogenase (E1), dihydrolipoyl transacetylase (E2), and dihydrolipoyl dehydrogenase (E3). In order to sense the cellular energy charge, two enzymes (i.e., the PDH kinase and the PDH phosphatase) are endowed with a variety of allosteric modulators and covalent modifiers. The TCA cycle comprises eight steps: a condensation of acetyl-CoA by enzyme CS, an isomerization of citrate by enzyme (aconitase), an oxidative decarboxylation of isocitrate by enzyme IDH, an oxidative

decarboxylation of α -KG by the multienzyme complex α -KGDH, a substrate-level phosphorylation of succinyl-CoA by enzyme SCS, a dehydrogenation of succinate by enzyme SDHA (SDHA is tightly bound to the mitochondrion inner membrane through the protein subunits SDHB, SDHC, and SDHD, which all constitute the complex II of the electron-transport chain), a hydration of fumarate by enzyme FH, and a dehydrogenation of malate by enzyme MDH to produce OAA. Energy in the form of ATP and NADH is produced at several points along the entire TCA cycle. Glu can enter the TCA cycle by either oxidative deamination catalyzed by GDH or transamination via the aspartate aminotransferase (AAT), an enzymatic reaction producing aspartate from OAA.

The Glutamate/GABA–Glutamine Cycle

The glutamate (Glu) released by a glutamatergic presynaptic terminal is mainly taken up into astrocytes, although a small portion could flood back into the terminal through the transporter GLT-1b. In the GABAergic synapse, the released GABA is taken up into both the presynaptic terminal and the astrocytes, with the former having higher affinity for the neurotransmitter. Inside the astrocyte, GABA is catabolized to succinate before entering the TCA cycle. The carbon skeleton of this amino acid exits the TCA cycle as α -KG, which is then transformed to glutamate. The Glu is amidated to glutamine (Gln) by glutamine synthetase, an enzymatic reaction that benefits adjacent tissues by consuming and detoxifying free ammonia. The synthesized glutamine returns to the presynaptic terminals of both glutamatergic and GABAergic neurons, with a preference for the former. In both terminals, glutamine is used to regenerate Glu and ammonia via phosphate-activated glutaminase (PAG). The regenerated Glu in the GABAergic presynaptic terminal is converted back into GABA via Glu decarboxylase (GAD).

Oxygen Transport

Since oxygen, unlike Glc, does not have specific transporters to enter the extravascular space, oxygen transport from blood to tissue is mainly driven

by diffusion. Diffusion-limited models suggest that blood flow is the only way by which tissue oxygen capacity can be increased (Buxton and Frank 1997; Gjedde 1997). The prediction of such diffusion-limited oxygen transport models is nonlinear coupling between blood flow and oxygen metabolism. Based on observed linear relationships between blood flow and oxygen metabolism (across regions, conditions, and/or species), other empirically derived models suggest facilitated diffusion through processes like altering number of perfused capillaries and/or intracapillary stacking of erythrocytes (Hyder et al. 1998, 2000). The general assumption in all of these models that all of the oxygen leaving the capillary is metabolized and that there is no oxygen back flux into the blood has been experimentally confirmed (Grieb et al. 1985; Kassissia et al. 1995; Herman et al. 2006).

Major Controversies

- What does underlie the brain functional hyperemia: subthreshold synaptic activity or spiking (Logothetis et al. 2001; Mukamel et al. 2005).
- Are the EEG brain sources purely dipolar in nature (Riera et al. 2012; Gratiy et al. 2013).
- Does oxidatively derived ATP contribute equally to postsynaptic and action potentials (Attwell and Laughlin 2001) across a range of activity levels and/or species (Hyder et al. 2013b)?

Definition

Adaptation is a change over time in the responsiveness to stimuli. In adaptation to stimulus statistics, this change is relative to statistical properties of the stimulus like the standard deviation. Biophysical models of this phenomenon are computational models of the components of a neuron or a circuit to show the mechanistic basis of adaptation.

Detailed Description

Computational models are instrumental to investigate and understand the mechanisms that shape the spike pattern of a neuron’s response given its synaptic inputs. They can complement experimental approaches by providing insights

into possible mechanisms. One important feature of many sensory systems is that they can adapt their response to the levels and context of the stimuli. Adaptation of the neuronal response is a process by which the responsiveness of the neuron changes as a result of previous stimulation. In the present case, we had experimentally studied adaptation mechanisms using a mechanosensory neuron of the leech *Hirudo medicinalis* known as the T neuron and built a computational model to further test some of the proposed mechanisms of adaptation to stimulus statistics (Arganda et al. 2007). Here we review how to use a simple two-compartment model to get insight into realistic mechanisms of bursting and adaptation.

An important function of adaptation in the T neuron is to mediate adaptive scaling of neuronal responses to stimulus statistics. Sensory systems have to deal with stimuli that fluctuate in time and even change their scale. A sensory neuron has a limited range of outputs, insufficient to represent all the stimulus values present in a natural context, which can span several orders of magnitude. To efficiently encode naturalistic stimuli, a neuron then needs to adapt its response to the stimulus variance, adjusting its output range to the range of inputs (Wark et al. 2007). This adaptive scaling to the variance of the stimulus distribution

enhances information transmission (Brenner et al. 2000; Sharpee et al. 2006).

Very simplified models, such as “integrate and fire,” are useful for neurons whose spiking output directly reflects the amplitude of the input. More complex responses as the ones discussed here (bursting and adaptation) require the explicit consideration of specific voltage-gated conductances and different biophysical mechanisms. While detailed multi-compartment models including all known conductances of the cell and the neuron’s geometry are more realistic (at least when we know all parameters in some detail), the large number of variables involved makes it difficult to isolate and understand the basic mechanisms responsible for a given response feature. An intermediate approach is to consider a biophysical model including the known experimental conductances of the neuron and look for the minimal ingredients necessary to reproduce a given behavior.

Following this idea, we simplified a detailed multi-compartment model of the mechanosensitive T neuron (Cataldo et al. 2005) and considered only two compartments (soma/axon and dendrite) represented as equivalent electrical circuits and including all known conductances of the T cell (Fig. 1a). Each compartment consists of a membrane capacitance $C = 1 \mu\text{F}/\text{cm}^2$

Biophysics of Adaptation in a Computational Model of the Leech T Neuron, Fig. 1 (a) Two-compartment model of the T neuron including known conductances and the Na⁺ pump. (b) Model response during a stimulation protocol consisting of a low-amplitude periodic train of

pulses followed by an epoch of high-amplitude pulses before returning to the initial, low-amplitude pulses (panel d, in red). (c) Model response after removing the Na⁺ pump

in parallel with the conductances associated to two inward currents (a fast Na^+ current, I_{Na} , and a high-threshold Ca^{2+} current, I_{Ca}); an outward persistent K^+ current, I_K ; a leak current, I_L ; and two outward currents solely regulated by intracellular Na^+ and Ca^{2+} pools, a Ca^{2+} -activated K^+ current, $I_{K,Ca}$, and the Na^+ pump, I_{pump} .

The voltage-dependent currents I_{Na} , I_K , and I_{Ca} are described by Hodgkin-Huxley-type equations. The properties of the Na^+ and K^+ currents were adjusted to reproduce the amplitude, duration, and shape of the action potential of the T cell, as well as the resting membrane potential and membrane time constant of the neuron. The conductance of the leakage channel, I_L , was chosen to obtain values of input resistance in the range of the experimental values. These currents are given by

$$I_{Na}^i = g_{Na} m_{Na}^3 h(V_i - V_{Na})$$

$$I_K^i = g_K n^2 (V_i - V_K)$$

$$I_{Ca}^i = g_{Ca} m_{Ca} (V_i - V_{Ca})$$

$$I_L^i = g_L (V_i - V_L),$$

where the index $i = s, d$ stands for soma or dendrite. Conductances (in mS/cm^2) and Nernst potentials (in mV) are the same for both compartments and are given in Table 1. The activating and inactivating gating variables m , n , and h evolve according to first-order kinetics, $\frac{dm(V_i)}{dt} = [m_\infty(V_i) - m(V_i)]/\tau_m(V_i)$, where the asymptotic values and time constants (in milliseconds) are taken from (Cataldo et al. 2005).

$$m_\infty Na(V_i) = \frac{1}{1 + e^{-(\gamma_i + 35)5}} \tau_{mNa} = 0.1$$

$$h_\infty(V_i) = \frac{1}{[1 + e^{(\gamma_i + 50)9}]^2}$$

$$\tau_h(V_i) = \frac{13.8}{1 + e^{(\gamma_i + 36)35}} + 0.2$$

$$n_\infty(V_i) = \frac{1}{1 + e^{-(\gamma_i + 22)9}}$$

$$\tau_n(V_i) = \frac{5}{1 + e^{(\gamma_i + 10)10}} + 1$$

$$m_{\infty, Ca}(V_i) = \frac{1}{1 + e^{-(\gamma_i + 10)2.8}} \tau_{m, Ca} = 0.6$$

The two outward currents $I_{K,Ca}$ and I_{pump} are modulated by activity and are therefore responsible for different adaptation processes. On the one hand, the Ca^{2+} -dependent K^+ current $I_{K,Ca}$ is fast (Wang 1998; Cataldo et al. 2005) and, in combination with the high-threshold, non-inactivating Ca^{2+} current I_{Ca} , is responsible for the bursting mechanism (Wang 1998; Kepecs et al. 2002). The role of the persistent inward current I_{Ca} is to produce a positive feedback on membrane potential, thus driving a high firing rate, whereas the activity-dependent current $I_{K,Ca}$ generates a slower negative feedback that terminates firing, thus producing a burst of action potentials. Therefore, the $I_{K,Ca}$ current mainly determines burst duration, and its parameters can be tuned to produce the burst duration distribution observed experimentally.

On the other hand, the Na^+ pump acts on a much slower time scale and is responsible for the long refractory times observed after sustained activity (Cataldo et al. 2005). As spiking activity is maintained, the concentration of Na^+ ions inside the cell increases, elevating the activity of the slow Na^+ outward current, I_{pump} . This generates a delayed negative feedback on the membrane

Biophysics of Adaptation in a Computational Model of the Leech T Neuron, Table 1 Nernst potentials and maximum conductances of the ionic currents used in the model

Currents	I_{Na}	I_K	I_{Ca}	I_L	$I_{K,Ca}$	I_{pump}
$V_{\text{Nernst}}(\text{mV})$	45	-62	60	-48	-62	-200
g (mS/cm^2)	350	90	0.5	0.1	3	0.5

potential, hyperpolarizing the membrane in an activity-dependent manner. When firing activity stops, the action of the pump decreases, allowing a slow recovery of the membrane potential.

The two currents modulated by the intracellular Ca^{2+} and Na^+ pools are given by

$$I_{K,Ca}^i = g_{K,Ca} k_{Ca} (V_i - V_k)$$

$$I_{\text{pump}}^i = g_{\text{pump}} k_{Na} (V_i - V_{\text{pump}})$$

where the dynamics of the ion-dependent conductances k_{Ca} and k_{Na} and of the ion concentrations is given by first-order kinetics (Yamada et al. 1998).

$$\frac{dk_{Ca}}{dt} = \frac{[Ca^{2+}] - k_{Ca}}{\tau_{k,Ca}}$$

$$\frac{d[Ca^{2+}]}{dt} = \frac{-[Ca^{2+}] - \alpha_{Ca} I_{Ca}}{\tau_{i,Ca}}$$

$$\frac{dk_{Na}}{dt} = \frac{[Na^+] - k_{Na}}{\tau_{k,Na}}$$

$$\frac{d[Na^+]}{dt} = \frac{-[Ca^{2+}] - \alpha_{Na} I_{Na}}{\tau_{i,Na}}$$

Note that the terms $\alpha_{Ca} I_{Ca}$, $\alpha_{Na} I_{Na}$ represent the increase in intracellular ionic concentrations due to influx of ions through specific channels (I_{Ca} and I_{Na} are negative) and that ion removal is exponential with decay constants $\tau_{i,Ca}$, $\tau_{i,Na}$. Strictly, removal of Na^+ ions should depend on the pump activity, I_{pump} . However, this contribution is very small compared to the influx of sodium due to the fast current, I_{Na} (because I_{pump} is on the order of few pA, while I_{Na} spans tenths of nA), and sodium removal can be modeled using an exponential decay. In the model, we do not consider diffusion of ions between compartments.

Time constants for removal of Ca^{2+} are $\tau_{i,Ca} = 1,250$ ms for soma and 1,000 ms for dendrite. The time constants for Na^+ removal are adjusted to reproduce the delay in response after prolonged periods of activity observed in real T neurons and are set to $\tau_{i,Na} = 16,000$ ms for soma and 20,000 ms for dendrite. Note that these time

constants are one order of magnitude larger than those for calcium to take into account the empirical observation that the decrease in excitability and recovery due to the Na^+ pump is much slower than that due to the $I_{K,Ca}$ (Jansen and Nicholls 1973; Cataldo et al. 2005).

The parameters α_{Na} and α_{Ca} give the proportion of the ionic currents contributing to the sodium and calcium pools, respectively, and are set to $\alpha_{Na} = 0.016$, $\alpha_{Ca} = 0.1$ for the somatic compartment and $\alpha_{Na} = 0.16$, $\alpha_{Ca} = 0.2$ for the dendritic one. Time constants for concentration-dependent conductances take the values $\tau_{k,Ca} = 10$ ms, $\tau_{k,Na} = 100$ ms for both compartments.

With these currents, the membrane potential of both compartments changes in time according to the equations:

$$-C \frac{dV_s}{dt} = I_L + I_{Na} + I_K + I_{Ca} + I_{K,Ca}^s + I_{\text{pump}}^s + g_c (V_s - V_d) / p$$

$$-C \frac{dV_d}{dt} = I_L + I_{Na} + I_K + I_{Ca} + I_{K,Ca}^d + I_{\text{pump}}^d + \frac{g_c (V_d - V_s)}{1 - p} - I_{\text{stim}}$$

where the indices s and d stand for soma and dendrite, respectively. The electrotonic coupling between compartments, given by the parameter g_c , and the ratio of soma to total membrane area, p , also modulate bursting dynamics (Kepecs et al. 2002; Izhikevich 2007). Within our simplified two-compartment model, we choose these parameters to mimic experimental burst sizes when stimulated by a random stimulus with Gaussian distribution and set $g_c = 1.5 \text{ mS cm}^{-2}$ and $p = 0.7$.

We inject in the dendritic compartment an electrical current I_{stim} with the same features than the mechanical stimulation delivered to real T cells: a slowly varying Gaussian white noise with a frequency cutoff and different standard deviations (Arganda et al. 2007). Note, however, that the mechano-electrical transduction processes are unknown and the amplitude and cutoff frequencies of the stimulus current are not directly comparable to those of the mechanical stimulation. Moreover, the T cell model responds with bursts

only to upstrokes of the stimulus (detects only positive slopes) contrary to the real T cell.

First, we tested if our model neuron was able to reproduce the behavior observed in experiments in response to simple stimulation protocols that hyperpolarize the membrane. We thus injected a current I_{stim} consisting of a train of low-amplitude pulses followed by a long period of high-amplitude periodic stimulation (Fig. 1d), before returning to the low-amplitude train. With the full model, the somatic membrane potential hyperpolarizes in a way similar to the real T cell neuron (Fig. 1b), inducing a latency period of no spiking until the basal resting potential is recovered. To see the role of the sodium pump on this behavior, we repeated the protocol in a model with the current I_{pump} absent from the equations (Fig. 1c).

This rendered a response similar to the T neuron treated with the drug strophanthidin, a sodium pump blocker (Arganda et al. 2007). The small gap that we observe in Fig. 1c is a consequence of the recovery time of the after-hyperpolarization current $I_{K, Ca}$, with a faster time scale than that of the sodium pump.

Once that we had properly modeled the hyperpolarization effect of the sodium pump, we could check its role on coding and adaptive scaling. First, we probed the dynamic range of the bursting neuron model stimulating the dendrite with random stimuli of different amplitudes. The full neuron model is able to respond with a large burst rate (in bursts per second) to moderate stimulus velocities (Fig. 2a) and only saturates at large velocities of the high-amplitude stimulus (green line).

Biophysics of Adaptation in a Computational Model of the Leech T Neuron, Fig. 2 Adaptive scaling of the two-compartment model. (a) Burst rate, $r(v)$, as a function of the stimulus velocity, v , in the two-compartment model, normalized by mean burst rate, r_{av} . Three random stimuli with different amplitudes (standard deviations σ) were used: $\sigma = 4.5$ nA (black line), $\sigma = 9$ nA (orange), and

$\sigma = 18$ nA (green). (b) Normalized burst rate as in (a) versus input velocity rescaled by the standard deviation of the stimulus velocity ensemble. (c) Probability distribution of velocities before bursts of two spikes, for the same stimulus ensembles. (d) Probability distributions prior to bursts of two spikes versus rescaled input velocity

When the input velocity is scaled by the width of the distribution of velocities, we see that burst rates code for a very similar range of scaled velocities independently of the stimulus statistics (Fig. 2b). This adaptive scaling holds for velocities as large as twice the standard deviation of the stimulus, demonstrating that our simple model is able to reproduce the experimentally observed statistical adaptation for burst rates.

Since the neuron also codes information about the stimulus velocity in the duration of bursts, we checked whether the burst code can also adapt to the stimulus statistics. We built the probability distribution of velocities prior to bursts of two spikes, for different stimulus ensembles (Fig. 2c). The probability range increases with

stimulus width (orange and green lines in Fig. 2c), but when velocities are normalized by the standard deviation, the velocity code spans the same range independently of the stimulus ensemble (Fig. 2d).

Next, we investigated the role of the sodium pump in the neuron coding properties. We repeated the stimulation protocols with three different ensembles, but in a model without the I_{pump} current (Fig. 3).

We see that the sodium pump affects both the dynamic range of the neuron response and the adaptive scaling to the stimulus distribution. First, we see that burst rates saturate much earlier (compare Figs. 3a and 2a) and the probability distribution of velocities before bursts span a narrower range (compare Figs. 3c and 2c). This

Biophysics of Adaptation in a Computational Model of the Leech T Neuron, Fig. 3 The sodium pump is responsible for adaptive scaling. (a) Burst rate as a function of the stimulus velocity in the two-compartment model without the sodium pump current, I_{pump} , for three Gaussian stimulus ensembles of different amplitude: $\sigma = 4.5$ nA (black line), $\sigma = 9$ nA (orange), and $\sigma = 18$ nA (green).

Compare to Fig. 2a. (b) Normalized burst rate versus input velocity rescaled by the standard deviation of the stimulus velocity ensemble. (c) Probability distribution of velocities before bursts of two spikes in the model without sodium pump. (d) Probability distributions prior to two spike bursts versus rescaled input velocity

suggests that the response dynamics without the sodium pump is restricted and probably not able to adapt the response to wide stimulus ensembles. This is indeed what we observe when we plot burst rates and probabilities versus the rescaled input velocities (Fig. 3b, d). The rescaled plots show a marked difference between the low- and high-amplitude ensembles especially at large velocities.

We thus conclude that slow activity-dependent hyperpolarization, as that induced by the sodium pump, is a general mechanism to enlarge the dynamic range of a neuron's response and achieve adaptation to the statistical context of the stimulus, providing the flexibility needed for changing real-world stimuli.

Definition

Boltzmann machines are usually defined as neural networks in which the input-output relationship is stochastic instead of deterministic (as it is in the original Hopfield network). Then, Boltzmann machines are normally defined as stochastic versions of the Hopfield model or other attractors neural networks. A main difference between Hopfield networks and Boltzmann machines lies in the fact that while in Hopfield networks the deterministic dynamics brings the state of the system downhill, toward the stable minima of some energy function related with some information content, in a Boltzmann machine such *prescribed* states of the system cannot be reached accurately due to stochastic fluctuations. For a

Boltzmann machine, then, the steady-state of the system is characterized by an equilibrium probability distribution to be in such states, which is given, as a function of the energy of such states, by the Boltzmann distribution. The inherent stochastic dynamics of Boltzmann machines allows the system sometimes to go uphill and, therefore, to have some probability to escape from undesirable local minima and reach a global minimum. In practice, this can be done using a *simulating annealing* procedure, that is, start the network dynamics at high temperature and decrease it until an equilibrium state is reached with energy fluctuating around the global minimum. Boltzmann machines are used, for instance, to retrieve or complete patterns distributed according to some predefined equilibrium distribution, and make use of *visible* units which are clamped to the patterns in the training set and *hidden* units which are free-running variables of the system. Boltzmann machines were invented by G. Hinton and T. Sejnowski (1983a, b).

Detailed Description

As in the Hopfield model, the simplest form of a Boltzmann machine is constituted by a network of N binary units or “neurons” whose state is represented by state variables $s_i = 1$ or 0 , $i = 1, \dots, N$. The main difference with Hopfield network arises in the fact that Boltzmann machine units are stochastic. Also, the Boltzmann machine is characterized by an “energy function” characterizing a particular configurational state of the network $\mathbf{s} = (s_1, \dots, s_N)$, and which is defined as in the Hopfield model, that is:

$$E(\mathbf{s}) = -\frac{1}{2} \sum_{\substack{i,j \\ i \neq j}} w_{ij} s_i s_j + \sum_i \theta_i s_i \quad (1)$$

where w_{ij} represents the weight or strength of the link or “synapse” connecting neuron i and j . w_{ij} is assumed to be symmetric, that is $w_{ij} = w_{ji}$ with $w_{ii} = 0$, and θ_i is a “bias” of unit i that represents an activation neuron threshold.

In a Boltzmann machine, the state of a given neuron i is determined by its total input current, or *local field*, defined as

$$h_i(t) = \sum_j w_{ij} s_j(t) - \theta_i,$$

where the bias term is assumed to be fixed. Then, the dynamics of the Boltzmann machine is implemented as follow: given the state of the network at time t , a neuron is chosen at random at time $t + 1$ from the population and its state is updated according with the probabilistic rule

$$\text{Prob}(s_i(t+1) = \sigma) = \frac{1}{1 + \exp[-(2\sigma - 1)\beta h_i(t)]}, \quad (2)$$

with $\sigma = 1, 0$, and $\beta = \frac{1}{k_B T}$ where k_B is the Boltzmann constant and T is a *temperature* parameter that drives the stochastic changes in the neurons. Expression (2) implements the so-called *Glauber dynamics* and can be obtained from the *Hamiltonian* or energy function (1) if one assumes that at each time t the configurational energy of the network is given by $E(\mathbf{s}(t))$. Then, a stochastic change at time t in the state of neuron i from $s_i = \sigma$ to $s_i = 1 - \sigma$ implies a change in this configurational energy given by

$$\begin{aligned} \Delta E_i(t) &= E(\mathbf{s}^i(t)) - E(\mathbf{s}(t)) \\ &= (2\sigma - 1) \left[\sum_j w_{ij} s_j(t) - \theta_i \right] \\ &= (2\sigma - 1) h_i(t). \end{aligned}$$

Here $\mathbf{s}^i(t)$ represents a network state in which the state of neuron i is $s_i(t) = 1 - \sigma$, assuming that the network state $\mathbf{s}(t)$ has $s_i(t) = \sigma$. Equation (2) finally is obtained when $\text{Prob}(s_i(t+1) = \sigma)$ is supposed to be given by the Boltzmann factor, that is

$$\text{Prob}(s_i(t+1) = \sigma) = \frac{e^{-\beta E(\mathbf{s}(t))}}{Z}, \quad (3)$$

where Z is obtained from normalization of Eq. (3), that is:

$$\text{Prob}(s_i(t+1) = \sigma) + \text{Prob}(s_i(t+1) = 1 - \sigma) = 1.$$

The last, then, implies

$$Z = e^{-\beta E(\mathbf{s}(t))} + e^{-\beta E(\mathbf{s}'(t))},$$

and therefore

$$\begin{aligned} \text{Prob}(s_i(t+1) = \sigma) &= \frac{e^{-\beta E(\mathbf{s}(t))}}{e^{-\beta E(\mathbf{s}(t))} + e^{-\beta E(\mathbf{s}'(t))}} \\ &= \frac{1}{1 + e^{-\beta[E(\mathbf{s}'(t)) - E(\mathbf{s}(t))]}} \end{aligned}$$

which has the form given by Eq. (2) using the definition of $\Delta E_i(t)$ above.

The use of Glauber dynamics (2) to describe stochastic changes in neurons in a Boltzmann machine allows to study its equilibrium properties using statistical physics techniques. One can assume, for instance, that this stochastic dynamics drives the Boltzmann machine state into a steady state which is described by a probability distribution $P(\mathbf{s})$. Let's consider as above two configurations or states of the network $\mathbf{s}$ and $\mathbf{s}'$ that differ only in the value that the neuron state s_i takes. Since stochastic changes in each neuron occur independently from the others and using Eq. (3), one has

$$\frac{P(\mathbf{s})}{P(\mathbf{s}')} = \frac{\text{Prob}(s_i = \sigma)}{\text{Prob}(s_i = 1 - \sigma)} = e^{-\beta[E(\mathbf{s}) - E(\mathbf{s}')]}, \quad (4)$$

which implies a steady state distribution

$$P(\mathbf{s}) = \frac{e^{-\beta E(\mathbf{s})}}{Z}. \quad (5)$$

The last has the form of the Boltzmann distribution with the normalization factor $Z = \sum_{\mathbf{s}} e^{-\beta E(\mathbf{s})}$ being the so-called *partition function*. Therefore, $P(\mathbf{s})$ as in Eq. (5) characterizes an equilibrium state of the Boltzmann machine described by the Hamiltonian $E(\mathbf{s})$.

Master Equation Description

Under the probabilistic rule (2), stochastic changes in neurons in a Boltzmann machine occur as in a Markov chain (van Kampen 1990). That is, the dynamics of the state of the network can be view as a Markovian stochastic process whose dynamics is governed by the *master equation*

$$\begin{aligned} \partial_t P_t(\mathbf{s}) &= \sum_i c(\mathbf{s}^i \rightarrow \mathbf{s}) P_t(\mathbf{s}^i) \\ &\quad - c(\mathbf{s} \rightarrow \mathbf{s}^i) P_t(\mathbf{s}), \end{aligned} \quad (6)$$

where $\mathbf{s} = (s_1, \dots, s_i, \dots, s_N)$ and $\mathbf{s}^i = (s_1, \dots, 1-s_i, \dots, s_N)$ are network states which differ in the value of one neuron state, and $c(\mathbf{s}^i \rightarrow \mathbf{s})$ is the transition probability from state $\mathbf{s}^i$ to $\mathbf{s}$. In fact, one has for a Boltzmann machine

$$c(\mathbf{s}^i \rightarrow \mathbf{s}) = \text{Prob}(s_i(t+1) = \sigma) \quad (7)$$

when $\mathbf{s} = (s_1, \dots, \sigma, \dots, s_N)$ and $\mathbf{s}^i = (s_1, \dots, 1-\sigma, \dots, s_N)$. Moreover, a sufficient condition to reach a steady state in Eq. (6) is

$$c(\mathbf{s}^i \rightarrow \mathbf{s}) P(\mathbf{s}^i) = c(\mathbf{s} \rightarrow \mathbf{s}^i) P(\mathbf{s})$$

which is equivalent to Eq. (4) and it is known as *detailed balance condition*. With the choice (7), this condition guarantees that the stationary distribution is $P(\mathbf{s}) = \frac{e^{-\beta E(\mathbf{s})}}{Z}$.

Mean-Field Boltzmann Machines

One can define the mean firing rate of neuron i as

$$m_i(t) \equiv \langle s_i \rangle_t = \sum_{\mathbf{s}} s_i P_t(\mathbf{s}),$$

and the derivative in time of this expression leads to

$$\partial_t m_i = \sum_{\mathbf{s}} s_i \partial_t P_t(\mathbf{s}).$$

Introducing the master equation (6) in the rhs of the last equation gives

$$\partial_t m_i = -2 \langle s_i c(\mathbf{s} \rightarrow \mathbf{s}^i) \rangle_t + \langle c(\mathbf{s} \rightarrow \mathbf{s}^i) \rangle_t,$$

where $\langle \cdot \rangle_t$ means an average over $P(\mathbf{s})$. Using Eq. (7) one gets after some algebra

$$\partial_t m_i = -m_i + \frac{1}{2} + \frac{1}{2} \left\langle \tanh \left(\frac{\beta h_i}{2} \right) \right\rangle_t.$$

The steady state of this dynamics leads to

$$m_i = \frac{1}{2} + \frac{1}{2} \left\langle \tanh \left(\frac{\beta h_i}{2} \right) \right\rangle$$

where now the average is performed over the stationary distribution $P(\mathbf{s})$. Finally using the mean field assumption $s_i \rightarrow m_i$ one obtains

$$m_i = \frac{1}{2} + \frac{1}{2} \tanh \left(\frac{\beta \left(\sum_j w_{ij} m_j - \theta_i m_i \right)}{2} \right),$$

which defines the steady-state mean-field equation for a Boltzmann machine.

Learning in Boltzmann Machines

Boltzmann machines are used to retrieve some particular global states (the training set) distributed according to some external given probability distribution over these states. For this purpose, it is necessary to train the network such that the final weights induce global minima in $E(\mathbf{s})$, associated with the training set and with the highest probabilities according with the external probability distribution. This task cannot be done in standard stochastic Hopfield networks with Hebbian weights since the obtained equilibrium distribution describes minima of the $E(\mathbf{s})$ related with global states, for instance, $\mathbf{s} = \xi$, only with second order correlations among units as maximum. In fact, in this case the minimization of Eq. (5) through gradient descent gives

$$\frac{\partial \ln P(\xi)}{\partial w_{ij}} = \beta \left[\xi_i \xi_j - \sum_{\mathbf{s}} P(\mathbf{s}) s_i s_j \right]. \quad (8)$$

This, in practice, prevents the network from learning global states with correlations that involve more than two units. Such higher order correlated states occur, for instance, in the well know XOR problem, where the global states to be retrieved involve correlations among 3 units. For a Hopfield network with $N = 3$, for instance, there are $2^3 = 8$ possible global states, each one with a probability $\frac{1}{8}$ to occur without previous learning. However, only the patterns (110), (101), (011) and (000) solve the XOR problem, which implies some particular three units structure to be learned by the network, which cannot be implemented by Eq. (8).

To consider higher order correlations to be learned by Boltzmann machines, it is necessary to separate units in the network in two sets, the so-called “visible” units, $v_i, i = 1, \dots, n$ with $n < N$ that are *clamped* during learning to the training set of vectors (which now have only n units) and the “hidden” units, $u_i = n + 1, \dots, N$ which are *free-running* variables of the system. The network state then is $\mathbf{s} = (v_1, \dots, v_n, u_{n+1}, \dots, u_N)$ and the equilibrium steady state distribution (5) can be written now as $P(\mathbf{s}) = P(\mathbf{v}, \mathbf{u})$. We can compute the marginal equilibrium probability distribution for visible units as follow

$$P(\mathbf{v}) = \sum_{\mathbf{u}} P(\mathbf{v}, \mathbf{u}) = \sum_{\mathbf{u}} \frac{e^{-\beta E(\mathbf{v}, \mathbf{u})}}{Z}$$

with

$$Z = \sum_{\mathbf{v}, \mathbf{u}} e^{-\beta E(\mathbf{v}, \mathbf{u})}.$$

$P(\mathbf{v})$ gives, then, the probability of visible units in the free-running system. However, we want these units to be distributed according to some desired probabilities $\bar{P}(\mathbf{v})$ which are the real probabilities of the training set or *environment*. An useful quantity to measure the difference between distributions $P(\mathbf{v})$ and $\bar{P}(\mathbf{v})$ is the Kullback–Leibler divergence or relative entropy (Kullback and Leibler 1951) defined as

$$G = \sum_{\mathbf{v}} \bar{P}(\mathbf{v}) \ln \frac{\bar{P}(\mathbf{v})}{P(\mathbf{v})},$$

which ever is positive or zero. Precisely, G has the minimum zero value when the equilibrium probability $P(\mathbf{v})$ coincides with the desired probability $\bar{P}(\mathbf{v})$. One can use this fact to find an algorithm which learns the training set or environment patterns using a gradient descent of G as follows

$$\Delta w_{ij} = -\eta \frac{\partial G}{\partial w_{ij}} = \eta \sum_{\mathbf{v}} \frac{\bar{P}(\mathbf{v})}{P(\mathbf{v})} \frac{\partial P(\mathbf{v})}{\partial w_{ij}} \quad (9)$$

with $\eta > 0$ being the learning rate and where it is used that the clamped probability $\bar{P}(\mathbf{v})$ is independent of w_{ij} . After some algebra (see for instance Ackley et al. (1985)) one finally obtains

$$\Delta w_{ij} = \eta \beta \left[\langle s_i s_j \rangle_c - \langle s_i s_j \rangle_f \right] \quad (10)$$

where $\langle s_i s_j \rangle_f \equiv \langle s_i s_j \rangle = \sum_{\mathbf{s}} P(\mathbf{s}) s_i s_j$ is the standard average over the equilibrium joint probability $P(\mathbf{s}) = P(\mathbf{v}, \mathbf{u})$ of the free-running system (without being clamped to any external environment state) and $\langle s_i s_j \rangle_c = \sum_{\mathbf{s}} \bar{P}(\mathbf{s}) s_i s_j$ is the average over the equilibrium joint probability $\bar{P}(\mathbf{s}) = \bar{P}(\mathbf{v}, \mathbf{u})$ when the visible units are clamped to the vectors of the external training set (i.e., the standard Hebbian learning term). It is worth noting that in Eq. (10) s_i can be either a visible or a hidden unit in the network.

Learning in Boltzmann machines, as it is given in Eq. (10), can be very slow in practice when many hidden layers are considered, a fact that increases the size of the network. In this case, the system needs a long time to reach its equilibrium distribution, particularly when the system is free-running due to the existence of many local minima. Then, many different approaches have been developed to decrease learning time. One of the most successful of these techniques is to consider some restrictions in the network topology, as in the so-called *restricted Boltzmann machines* where the *visible-visible* or the *hidden-hidden* connections are not permitted, being the

connections between the visible and hidden neurons the only ones allowed.

|-----------|---|
| Attention | A general concept covering all factors that influence selection mechanisms, whether they are scene-driven and bottom-up or expectation-driven and top-down. |
| Salience | Parts of a stimulus (e.g., image, video, audio) that appear to an |

	observer to stand out, relative to their neighboring parts. It is a subjective perceptual quality.
Gaze	A coordinated motion of the eyes and the head that is long enough to concentrate on something. It is a key property of attention in natural behavior.
Scene free-viewing	A task in which participants are asked to look at an image, without any specific instruction. As a default scene analysis task, the free viewing paradigm offers a wealth of insights regarding the cues that attract attention.

Detailed Description

History, Scope, and Organization

Deciphering the computational mechanisms by which the brain deals with the computational complexity of an overwhelmingly high volume of incoming data (at a rate of 10^8 bits/s (Koch et al. 2006)) and how the brain programs eye movements continue to be important problems in neuroscience. Where humans look in images and videos provides important clues regarding how they perceive static (still images) and dynamic scenes (videos), locate the main focus of the image, recognize actions or events, and identify the main participants.

A significant amount of behavioral and computational research on attention has revealed that attention is deployed in two ways: bottom-up (BU) and top-down (TD). The bottom-up component of attention, aka endogenous or stimulus-driven, processes sensory information primarily in a feed-forward manner. Typically, a series of successive transformations are applied to the input visual signal to highlight the most interesting, important, conspicuous, or so-called *salient* regions (Itti and Koch 2001a; Koch and Ullman 1985). In contrast, in top-down attention, aka context-driven or goal-driven, information related to the ongoing behavior, task, or goal is selected (e.g., staying within the road lanes while driving (Land and Lee 1994)). The reader is referred to

Ballard et al. (1995), Borji et al. (2014), Hayhoe and Ballard (2005), Land and Hayhoe (2001), and Navalpakkam and Itti (2005) for reviews of top-down attention studies. Please see also the chapter on top-down attention in this encyclopedia (Schwedhelm and Treue 2015).

Conventionally, bottom-up attention models generate a 2D topographic saliency map, where a value at every location determines how salient that location is, relative to its neighbors. The goal in saliency modeling is then to transform an image into its spatially corresponding saliency map (static saliency), possibly also taking into account temporal relations between successive video frames of a movie (dynamic saliency) (Itti et al. 1998). Early computational saliency models were primarily concerned with identifying conspicuous regions due to low-level feature contrast (e.g., pop-out search). Gradually, however, saliency models have shifted from identifying low-level conspicuous image regions, regardless of where people look (as was the goal in Itti et al. (1998)), to predicting eye movements as a proxy for visual saliency (as was the goal in Bruce and Tsotsos et al. (2005)). Notice that eye movements are only one way of defining the saliency concept and testing saliency models. There is, however, a subtle distinction between the two. Please see Borji et al. (2013b) for a detailed discussion on this. Nonetheless, the recent trend in modeling bottom-up attention and saliency has encouraged researchers to collect increasingly larger eye movement datasets, in particular during free-viewing of natural scenes.

To frame the concepts and models of bottom-up attention so far into a broader picture, we refer to Fig. 1 as a possible anchor to help organize this review. The computational modeling effort will be reviewed in four phases:

- **Phase I:** This phase regards the early computational works (e.g., Koch and Ullman in 1985; Fig. 1a) closely built on top of behavioral hypotheses (e.g., the Feature Integration Theory by Triesman and Gelade).
- **Phase II:** Models in this phase extend and operationalize Phase I models to be applicable

Bottom-Up Attention, Models of, Fig. 1 (continued)

to an unconstrained variety of stimuli (e.g., Itti et al. model in 1998; Fig. 1b). The Itti et al. model spurred a lot of ideas resulting in a myriad of saliency models in phase III.

- **Phase III:** The spectral residual model by Hou and Zhang in 2007 is an example of models in this phase (see Fig. 1c for details on this model). It is a simple model and can be implemented in few lines of code.
- **Phase IV:** Recently, the resurgence and success of neural networks (NN) in computer vision and other areas has brought along a new wave of highly predictive saliency models (Phase IV; Fig. 1d). A notable example here is the SALICON model (Huang et al. 2015), proposed in 2015, in conjunction with the SALICON dataset (Jiang et al. 2015). It is the first model to be trained on a large scale attention dataset.

The principal emphasis in this chapter will be on computational models that can process any visual stimulus in the form of a still image and return a prediction map, the same size as the input image, that can be compared to human or animal behavioral or physiological responses (typically fixations during a task such as free viewing in the context of bottom-up attention) (Rothenstein and Tsotsos 2008). In addition to these models, some other types of models including abstract models, phenomenological models, or models specifically designed for a single task or for a restricted class of stimuli also exist, but will not be covered here

(see Gottlieb and Balan 2010; Itti and Koch 2001a; Rothenstein and Tsotsos 2008; Tatler et al. 2011).

Bottom-up attention models carry value for at least two main purposes. First, they present testable predictions that can be utilized for understanding human attention mechanisms at computational, behavioral, and neural levels. Indeed, a large number of cognitive studies have utilized saliency models for model-based hypothesis testing (e.g., Borji et al. 2013b; Parkhurst et al. 2002). Second, predicting where people look in images and videos is useful in a wide variety of applications across several domains (e.g., computer vision, robotics, neuroscience, medicine, assistive systems, healthcare, and human-computer interaction). Some example applications include gaze-aware compression and summarization, image enhancement, activity recognition, object segmentation, recognition and detection, image captioning, visual question answering, advertisement design, novice training, patient diagnosis, and surveillance. See Borji and Itti (2013) for a review.

In what follows, we first examine key concepts of early bottom-up attention models (section “Bottom-Up Attention Modeling: Pre Deep Learning Era”), followed by a brief overview of deep saliency models (section “Bottom-Up Attention Modeling: Deep Learning Era”), and a discussion of biological plausibility of deep and non-deep saliency models (section “Biological Plausibility of Classic and Deep Saliency

Bottom-Up Attention, Models of, Fig. 1 Four models from four different eras of saliency modeling. **(a) Phase I:** Koch and Ullman (1985) introduced the concept of a saliency map derived from bottom-up inputs from all feature maps, where a winner-take-all (WTA) network selects the most salient location for further processing. **(b) Phase II:** Itti et al. (1998) proposed a complete computational implementation of a purely bottom-up and task-independent model based on Koch & Ullman’s theory, including multiscale feature maps, saliency map, winner-take-all, and inhibition of return. **(c) Phase III:** A myriad of saliency models appeared between 1998 and 2013. Schematic representation of spectral residual model (Hou and Zhang 2007) by Hou and Zhang (2007). The log

spectrum $\mathcal{L}(f)$ is computed from the down-sampled image (with amplitude $\mathcal{A}(f)$ and phase $\mathcal{P}(f)$). From $\mathcal{L}(f)$, the spectral residual $\mathcal{R}(f)$ is obtained by multiplying $\mathcal{L}(f)$ with a local average filter and subtracting the result from itself. The saliency map is then the inverse Fourier transform of the exponential of amplitude plus phase (i.e., $\mathcal{S}(x) = \mathcal{F}^{-1}[\exp(\mathcal{R}(f) + \mathcal{P}(f))]$). **(d) Phase IV:** A new wave of saliency models has emerged with the resurgence of convolutional neural networks (CNNs). Huang et al. (Huang et al. 2015) proposed a deep saliency model, known as the SALICON, that combines information from two pretrained CNNs, each on a different image scale (fine and coarse). The two CNNs are then concatenated to produce the final saliency map

Models”). In section “[Benchmarks, Datasets, and New Data Collection Methodologies](#),” current saliency benchmarks, datasets, and new methodologies for collecting large scale data are explained. In section “[State-of-the-Art Performance](#),” we provide a quantitative comparison of a large number of deep and non-deep saliency models in their ability to predict eye movements during free viewing of natural scenes. Section “[Where Do Models Fail?](#)” explores what current models are missing. Finally, in section “[Discussion and Outlook](#),” we discuss the remaining challenges that need to be addressed in order to build better saliency models.

Bottom-Up Attention Modeling: Pre-deep Learning Era

Computational modeling of bottom-up attention dates back to the seminal theoretical works by Treisman and Gelade (1980), the computational architecture by Koch and Ullman (1985), and the bottom-up model of Itti et al. (1998). Itti et al.’s model was able to predict human behavior in visual search tasks (e.g., pop-out versus conjunctive search (Itti and Koch 2000)), demonstrate robustness to image noise (Itti et al. 1998), detect traffic signs and other salient objects in natural environments (Itti and Koch 2001b), detect pedestrians in natural scenes (Miau et al. 2001), locate military vehicles in overhead imagery (Itti et al. 2001), and – most importantly – predict where humans look during passive viewing of images and videos (Parkhurst et al. 2002; Peters et al. 2005). Note that visual salience does not only depend on the physical property of a visual stimulus. It is a consequence of the interaction of a stimulus with other stimuli, as well as with a visual system (biological or artificial). For example, a color-blind person may have a dramatically different experience of visual salience than a person with normal color vision.

Following initial success, many research groups started exploring the notions of bottom-up attention and visual salience, which gave rise to many computational models from 1998 to 2013. In 2013, we summarized 53 bottom-up models along 13 different factors (Borji and Itti 2013; Borji et al. 2013a). These models fall into

different categories (e.g., Bayesian, learning-based, spectral, and cognitive). The early models mainly computed visual salience from bottom-up features in several feature maps, including luminance contrast, red-green and blue-yellow color opponency, and oriented edges (Itti et al. 1998). Subsequent models incorporated mid- and higher level features (e.g., face and text (Cerf et al. 2009), gaze direction (Parks et al. 2015)) to better predict gaze. A thorough examination of all models in this period is certainly not feasible in this limited space. Instead, we list a number of highly influential static and dynamic saliency models as follows. These include both models that are strongly inspired by biological vision as well as other implementations of saliency that are based on more abstract mathematical definitions.

1. **Static saliency models:** Attention for Information Maximization (AIM) (Bruce and Tsotsos 2005), Graph-based Visual Saliency (GBVS) (Harel et al. 2006), Saliency Using Natural statistics (SUN) (Zhang et al. 2008), Spectral Residual saliency (SR) (Hou and Zhang 2007), Adaptive Whitening Saliency (AWS) (Garcia-Diaz et al. 2012), Boolean Map-based Saliency (BMS) (Zhang and Sclaroff 2013), and the Judd et al. model (Judd et al. 2009).
2. **Dynamic saliency models:** AWS-D (Leboran et al. 2017), OBDL (Hossein Khatoonabadi et al. 2015), Xu et al. (2017), PQFT (Guo et al. 2008), and Rudoy et al. (2013).

Bottom-Up Attention Modeling: Deep Learning Era

Deep learning has emerged as a very successful solution to a variety of problems across several computational domains (LeCun et al. 1998). A deep-learning architecture is a cascade of simple modules that compute nonlinear input–output mappings, and all (or most) of which are subject to learning. A certain type of deep architectures, known as convolutional neural networks (CNN, aka ConvNets) has been very popular. A typical CNN is composed of a series of convolutional layers and pooling layers, followed by one or more fully connected layers. The parameters of the entire network are learned via

backpropagation over a large scale labeled dataset for a certain task (e.g., object recognition). The overall architecture of CNNs resembles the LGN-V1-V2-V4-IT hierarchy of the visual ventral stream, and the convolutional and pooling layers are directly inspired by the classic notions of simple cells and complex cells in the cortex (e.g., Yamins and DiCarlo 2016).

The success of CNNs on large scale object recognition corpuses (Deng et al. 2009) has brought along a new wave of saliency models that perform markedly better than traditional saliency models based on hand-crafted features. To model bottom-up attention, researchers leverage existing deep architectures that are trained for scene or object recognition and repurpose them to predict saliency. Often some architectural novelties are also introduced. These models are trained in an end-to-end manner, effectively formulating saliency as a regression problem. To remedy the lack of sufficiently large scale fixation datasets, deep saliency models are often pretrained on large image datasets and are then fine-tuned on small scale eye movement or click datasets. This procedure allows models to reuse the object-level visual knowledge already learned in CNNs and successfully transfer them to the task of saliency prediction. A large number of deep saliency models have appeared in a relatively short period of time (2014–2018). A detailed discussion of these models goes beyond the scope of this chapter. Instead, we include a number of landmark static and dynamic deep saliency models and refer the reader to Borji (2018), for a comprehensive review. These models differ in their architectures and the way they are trained.

1. **Static saliency models:** eDN (Vig et al. 2014), DeepGaze I and II (Kümmerer et al. 2014), Mr-CNN (Liu et al. 2015), SALICON (Huang et al. 2015), DeepFix (Kruthiventi et al. 2017), SAM-ResNet (Cornia et al. 2016), and EML-Net (Jia 2018).
2. **Dynamic saliency models:** Two-stream network (Bak et al. 2018), Chaabouni et al. (2016), Bazzani et al. (2016), OM-CNN (Jiang et al. 2017), Gorji and Clark (2018), ACLNet (Wang et al. 2018), and SG-FCN (Sun et al. 2018).

To account for differences in viewing static and dynamic stimuli by human observers (Observers view images and videos differently. They have much less time to view each video frame (about 1/30 of a second) compared to 3–5 s over still images. Further, motion is a key component that is missing in still images but strongly attracts human attention over videos (See Rudoy et al. 2013)), traditional video saliency models pair bottom-up feature extraction with an ad hoc motion estimation method that can be performed either by means of optical flow or feature tracking. In contrast, deep video saliency models learn the entire process end-to-end, either by adding temporal information to CNNs (as in (Bak et al. 2018)), or developing a dynamic structure using recurrent neural networks (Hochreiter and Schmidhuber 1997) (as in (Bazzani et al. 2016)).

Biological Plausibility of Classic and Deep Saliency Models

How well do classic and deep saliency models agree with biological findings on visual attention mechanisms? To answer this question, we would like to highlight two key points. First, as explained above, previous research has shown that CNNs can explain the feed-forward mechanisms involved in rapid object recognition (Yamins and DiCarlo 2016). Second, since deep saliency models are built on top of CNNs, they inherit biologically plausible properties of CNNs (e.g., convolution operation). While it is not entirely clear how saliency is computed in these models and whether they work similar to traditional saliency models (e.g., by implementing center-surround operations, normalization, etc.; see Fig. 8), there is evidence that they may generalize classic models. To get an idea, consider a CNN with a single convolutional layer followed by a fully connected layer trained to predict fixations. This model generalizes the classic Itti model and also models built upon it that learn to combine feature maps (e.g., Borji 2012; Judd et al. 2009; Xu et al. 2014). The learned features in the CNN will correspond to orientation, color, intensity, etc., which can be combined linearly by a fully connected layer (or 1x1 convolutions in a fully convolutional neural network). To handle the

scale dependency of saliency computation, classic models often utilize multiple image resolutions. In addition to this technique (as in the SALICON model), deep saliency models concatenate maps from several convolutional layers (as in ML-Net), or combine input from earlier layers in the network with later layers (e.g., using skip connections) to preserve fine details.

Despite the above resemblances, the most evident shortcoming of classic models (e.g., the Itti model) with respect to today's deep architectures is the lack of ability to extract higher level features, objects, or parts of objects. Some classic models remedied this shortcoming by explicitly incorporating object detectors such as face or text detectors. The hierarchical deep structure of CNNs (e.g., 152 layers in the ResNet (He et al. 2016)) allows capturing complex cues that attract gaze automatically. This is perhaps the main reason behind the big performance gap between the two types of models. In practice, however, research has shown that there are cases where classic saliency models win over the deep models (Huang et al. 2015), indicating that current deep models still fall short in fully explaining low-level saliency (See Fig. 8). Further, deep models still fail in capturing some high-level attention cues (e.g., gaze direction, objects of action, relative importance of objects; See Fig. 7).

Our understanding of how saliency computation emerges inside deep saliency architectures and how the mechanisms involved in these models differ from those implemented in deep models for object recognition are still limited. In this regard, recent work on understanding the representations learned by CNNs for scene and object recognition can offer new insights to understand deep saliency models (e.g., He et al. 2019; Zhou et al. 2014).

Benchmarks, Datasets, and New Data Collection Methodologies

Benchmarks have been instrumental for advances in computer vision (Borji 2018). In the saliency domain, they have sparked a lot of interest and have spurred a lot of interesting ideas over the past several years. Two of the most influential image-

based benchmarks include MIT (saliency.mit.edu) and SALICON (<http://salicon.net>).

The MIT benchmark is currently the gold standard for evaluating and comparing image-based saliency models. It supports eight evaluation measures for comparison and reports results over two eye movement datasets: (1) MIT300 and (2) CAT2000 (Borji and Itti 2015). As of October 2018, 85 models are evaluated over the MIT300 dataset, out of which 26 are NN-based models (~30% of all submissions). The CAT2000 dataset has 30 models evaluated to date (9 are NN-based). In addition, five baselines are computed on both datasets. The SALICON benchmark is relatively new and is primarily based on the SALICON dataset (Huang et al. 2015). It offers results over seven scores and uses the same evaluation tools as the MIT benchmark. These two benchmarks are complementary to each other. The former evaluates models with respect to actual fixations but suffers from small scale data. The latter fixes the scale problem but considers noisy click data as a proxy of attention. In this review, we provide an overview of the SALICON dataset, since it has been very useful for constructing saliency models, but focus on providing results over the MIT benchmark since fixations provide a closer link to visual attention mechanisms than mouse clicks (Tavakoli et al. 2017).

Traditionally, saliency models have been validated by comparing their outputs on small scale datasets composed of eye movements of humans or monkeys watching complex image or video stimuli (e.g., Bruce and Tsotsos 2005; Parkhurst et al. 2002). New large scale databases have emerged by following two trends: (1) increasing the number of images and (2) introducing new measurements to saliency by providing contextual annotations (e.g., image categories, regional properties, etc.). To annotate these large scale datasets, researchers have resorted to crowd-sourcing schemes such as gaze tracking using webcams (Xu et al. 2015) or mouse movements (Jiang et al. 2015; Kim et al. 2017) as alternatives to lab-based eye trackers (Fig. 2). Deep-supervised saliency models rely heavily on these sufficiently large and well-labeled datasets. Here, we provide an overview of the most recent and popular image

Bottom-Up Attention, Models of, Fig. 2 Left: New crowd-sourcing methodologies to collect attention data including TurkerGaze (Xu et al. 2015), SALICON (Jiang et al. 2015), and BubbleView (Kim et al. 2017). Right: (a) An illustration of BubbleView (Kim et al. 2017) paradigm, (b): The NSS score obtained by comparing mouse clicks and mouse movements to ground truth fixations on natural images on the OSIE dataset (Xu et al. 2014). Each point

represents the score obtained for a given number of participants, averaged over 10 random splits of participants and all 51 images used. It shows that BubbleView clicks better approximate fixations than SALICON mouse movements for all feasible numbers of participants ($n < 60$). It also shows that the clicks of 10 participants explain 90% of fixations (Figure compiled from Kim et al. 2017).

datasets for training and testing saliency models. For a review of fixation datasets pre-deep learning era please consult (Winkler and Subramanian 2013).

- **MIT300:** This dataset is a collection of 300 natural images from the Flickr Creative Commons and personal collections (Bylinskii et al. n.d.). It contains eye movement data of 39 observers, which results in a fairly robust ground-truth to test models against. It is a challenging dataset for saliency models, as images are highly varied and natural. Fixation maps of all images are held out and used by the MIT Saliency Benchmark for evaluating models.
- **CAT2000:** Released in 2015, this is a relatively larger dataset consisting of 2000 training images and 2000 test images spanning 20 different categories such as Cartoons, Art, Satellite, Low resolution images, Indoor, Outdoor, Line drawings, etc. (Bylinskii et al. n.d.). Images in this dataset come from search engines and computer vision datasets. The training set contains 100 images per category and has fixation annotations from 18 different observers. The test, used for evaluation, contains the fixations of 24 observers. Both MIT300 and CAT2000 datasets are collected using the EyeLink1000 eye-tracker.
- **SALICON:** It is currently the largest crowd-sourced saliency dataset. Images of this dataset come from the Microsoft COCO dataset and contain pixelwise semantic annotations. The SALICON dataset contains 10,000 training images, 5,000 validation images and 5,000 test images. Mouse movements are collected using Amazon Mechanical Turk via a psychophysical paradigm known as *mouse-contingent saliency annotation* (Fig. 2). Eye movements sometimes do not match mouse movements (Tavakoli et al. 2017). Nevertheless, this dataset introduces an acceptable and scalable method for the collection of additional data for saliency modeling. Currently, many deep saliency models are first trained on the SALICON dataset and are then fine-tuned on the MIT1000 or CAT2000 datasets for predicting fixations. A similar paradigm known

as the BubbleView (Kim et al. 2017) has also been proposed where a subject has to successfully click on a blurred image to reveal the story of the scene.

State-of-the-Art Performance

A quantitative comparison of static saliency models over the MIT benchmark is presented here (For detailed results please refer to (Borji 2018)). Since our concentration is on the ability of models to predict saliency measured via eye movements, we do not report results on the SALICON dataset.). The MIT benchmark has the most comprehensive set of traditional and deep saliency models evaluated over eight scores. We mainly focus on performances using the AUC-Judd and NSS scores since they provide a better model assessment than others (Bylinskii et al. 2018). The following five baselines are also considered:

1. **Infinite humans:** How well a fixation map of infinite observers predicts fixations from a different set of infinite observers, computed as a limit? See Bylinskii et al. (2018) for details. Prediction is still not perfect due to observer differences.
2. **One human:** How well a fixation map of one observer (taken as a saliency map) predicts the fixations of the other $n - 1$ observers. This is computed for each observer in turn, and averaged over all n observers. Different individuals are more or less predictive of the rest of the population, and so a range of prediction scores is obtained.
3. **Center:** This saliency model is computed by stretching a symmetric Gaussian to fit the aspect ratio of a given image, under the assumption that the center of the image is most salient (Tatler 2007).
4. **Permutation control:** For each image, instead of randomly sampling fixations, fixations from a randomly sampled image are chosen as the saliency map. This process is repeated five times per image, and the average performance is computed. This method allows capturing observer and center biases that are independent of the image (Koehler et al. 2014).

5. **Chance:** A random uniform value is assigned to each image pixel to build a saliency map. Average performance is computed over five such chance saliency maps per image.

Model Comparison over the MIT300 Dataset

Figure 3 shows the model performance over the MIT300 dataset. According to the AUC-Judd and NSS scores, the top five models are all NN-based. Using the AUC-Judd measure, DeepGaze II, and EML-NET models hold the top two spots. The *infinite humans* baseline performs the best. While models perform close to each other according to the AUC-Judd score, switching to NSS widens the differences. EML-NET has the highest score. The *infinite humans* baseline achieves the best NSS. The second and third ranks here belong to CEDNS and DPNSal models. BMS is the best-performing non-NN-based model and ranks better than the deep eDN model. The majority of models significantly outperform all the baselines, except the *infinite humans* baseline. Among baselines, *one human* and *center* predict fixations better than *permutation* and *chance*. For details please see Borji (2018).

Majority of the top 30 models are NN-based. Comparing the best results pre- and during the deep learning era shows significant improvements in terms of NSS and AUC scores. At the same time, the gap between the best model and the *infinite humans* baseline has also reduced.

Model Comparison over the CAT200 Dataset

Figure 4 shows the results over the CAT2000 dataset. According to the AUC-Judd measure, SAM-ResNet, SAM-VGG, and CEDNS are tied in the top but still below the *infinite humans* baseline. EML-NET, the winner on the MIT300 dataset, is ranked second here (tied with DeepFix). Switching to NSS, CEDNS performs slightly better than SAM-ResNet, SAM-VGG, and EML-NET. Among classic models, BMS (Zhang and Sclaroff 2013) and EYMOL (Zanca and Gori 2017) perform better than the others. Overall, models that do well over the MIT300 dataset perform well here as well.

There is a 3.5% improvement from the best non-deep model to the best deep model in terms

of AUC-Judd. The performance gap between the best non-deep model and the *infinite humans* upper-bound is 5.55% and shrinks to 2.22% using the best deep learning model (based on the AUC-Judd measure).

A qualitative comparison of model predictions over a sample image from the CAT2000 dataset is presented in Fig. 5. It shows large differences in appearance of the maps generated by different models. As it can be seen, recent deep models generate saliency maps that are very similar to the ground truth fixation map on this image, better than their non-deep predecessors.

Overall, results show that new neural network-based saliency models have created a large gap in performance relative to traditional saliency models from the pre-deep learning era. However, they still fall short in performing at the level of humans on this task as is demonstrated in Fig. 6. Further, they suffer from several shortcomings that need to be addressed, and will be discussed next.

Where Do Models Fail?

As we saw above, deep learning models have shown impressive performance in saliency prediction. A deeper look, however, reveals that they continue to miss key elements in images (Fig. 7).

In Bylinskii et al. (2016), we investigated the state-of-the-art image saliency models using a fine-grained analysis on image types, image regions, etc. In a behavioral study, conducted via Amazon Mechanical Turk, workers were asked to label (1 out of 15 choices) image regions that fall on the top 5% of the fixation heatmap. Analyzing the failures of models on those regions shows that the majority of the errors made by models are due to failures in accurately detecting parts of a person, faces, animals, text, objects of action, and gaze direction. These regions carry the greatest semantic importance in images (Fig. 7a & b). One way to ameliorate such errors is to train models on more instances of faces (e.g., partial, blurry, small, or occluded faces, non-frontal views), more instances of text (different sizes and types), and animals. Saliency models may also need to be trained on different tasks, to learn to detect gaze and action and leverage this information for

B

Bottom-Up Attention, Models of, Fig. 4 Performance of 30 saliency models and 5 baselines (marked with dashed red lines) for fixation prediction over the CAT2000 dataset.

Models are sorted in terms of the AUC-Judd (top row) and NSS (bottom row) scores. Infinite h. stands for *infinite humans* baseline

Bottom-Up Attention, Models of, Fig. 5 Saliency prediction maps of 35 models (including 5 baselines) on a sample image from the CAT2000 dataset (See the MIT benchmark webpage: saliency.mit.edu). Red boxes illustrate baselines

saliency. Moreover, saliency models need to reason about the relative importance of image regions, such as focusing on the most important person in the room or the most informative sign on the road (Fig. 7c, d & e). Interestingly, when we added the missing regions to models, performance improved drastically (Bylinskii et al. 2016). This

has been corroborated by several other studies that showed augmented deep saliency models perform better than original models (e.g., Gorji and Clark 2017, 2018; Recasens et al. 2015). Previous research has also identified cases where deep saliency models produce counterintuitive results relative to models based on feature

Bottom-Up Attention, Models of, Fig. 6 Performance of five baselines and the best saliency model (can be different for each score) for predicting fixations over two eye movement datasets (MIT300 and CAT2000) using eight scores. For EMD and KL, the lower the better (downward arrows). As it can be seen, the best model

often wins over the baselines except *infinite humans* baseline, indicating a gap between the best models and humans in saliency prediction. The gap is wider for some scores (e.g., NSS, EMD) and narrower using some other scores (e.g., AUC-Borji, sAUC). This holds over both datasets

contrast. For example, Rahman and Bruce (2015) and Huang et al. (2015) showed that, unlike the classic Itti et al. model, new saliency models fail to highlight odd items in pop-out psychological patterns (Fig. 8).

Discussion and Outlook

Saliency prediction performance has improved dramatically in the last few years, in large part, due to deep supervised learning and large scale mouse click datasets. We also have a much better understanding of challenges pertaining to model evaluation than before. The new NN-based models are trained in a single end-to-end manner, combining feature extraction, feature integration, and saliency value prediction, and have created a large gap in performance relative to traditional

saliency models. The success of these saliency prediction models suggests that the high-level image features encoded by deep networks (e.g., sensitivity to faces, objects and text), as well as the ability of CNNs to capture global context are extremely useful for predicting fixation locations. Despite the immense recent progress, however, saliency prediction is far from being solved and there continues to be a big room for improvement. Some areas in which improvement can be made are discussed below:

- Saliency models based on deep learning are good face and text detectors, much better than their non-deep predecessors. The degree to which these models perform in face and text detection, compared to the state-of-the-art face

Bottom-Up Attention, Models of, Fig. 7 (continued)

B

Bottom-Up Attention, Models of, Fig. 8 Example stimuli where deep saliency models produce counterintuitive results relative to models based on feature contrast. Sometimes deep models neglect low-level image features (local contrast) and overweight the contribution of high-level features (e.g., faces or text). Some of the failure cases might be due to the fact that deep saliency models compute

absolute saliency and not relative saliency (See section “[Biological Plausibility of Classic and Deep Saliency Models](#)”). Although fixations are not recorded on these images, it is easy to predict where participants will typically fixate. See Huang et al. (2015); Rahman and Bruce (2015) for more details

and text detectors, still remains to be determined.

- Even the best saliency models tend to place a disproportionate amount of importance on face regions, humans, and text even when they are not necessarily the most semantically interesting parts of the image. Saliency predictors will need to reason about the relative importance of image regions, such as focusing on the most important person in the room or the most informative sign on the road (which is image- and context-dependent). Similarly, in the presence of several text regions in the image, some high-level understanding of meanings is necessary to prioritize different text regions (e.g., what is the warning sign about?).
- There has been a lot of progress in understanding the representations learned by CNNs for scene and object recognition in recent years (e.g., Zhou et al. 2014). Our understanding of what is learned by deep saliency models, however, is limited. The main questions here are how saliency computation emerges inside deep saliency architectures, and how the patterns in different network layers learned for saliency

prediction differ from those patterns learned for object recognition? We have recently started to look into this (See He et al. 2019).

- Fair saliency model comparison still remains an unsolved research problem today. Active research is ongoing to understand the pros and cons of the saliency measures (e.g., Kummerer et al. 2018). Many of the current saliency methods compete closely with one another at the top of the existing benchmarks and performances vary in a narrow band (See Figs. 3 and 4). Also, as we saw in section “[State-of-the-Art Performance](#),” some evaluation measures have begun to saturate and the produced rankings by different models are often inconsistent with each other. Thus, as the number of saliency models grows and score differences between models shrink, evaluation measures should be adjusted to a) elucidate differences between models and fixations (e.g., by taking into account the relative importance of spatial and temporal regions) and b) mitigate sensitivity to map smoothing and center-bias. Complementary to measures, finer-grained stimuli such as image

Bottom-Up Attention, Models of, Fig. 7 While deep learning models have shown impressive performance for saliency prediction, a finer-grained analysis shows that they miss key elements in images. Some example stimuli for which models (here DeepFix model (Kruthiventi et al. 2017)) under- or overestimate fixation locations due to gaze direction (a), or locations of implied action or motion

(b) are shown. Also, models fail to detect small faces or profile ones, and fail to assign correct relative importance to them (c). Cases for which models do not correctly assign relative importance to people (d), or text regions (e) in the scene are also shown. Please see text and Bylinskii et al. (2016) for further details

Bottom-Up Attention, Models of, Fig. 9 A finer-grained test proposed in Bylinskii et al. (2016) for determining how saliency models prioritize different subimages in a panel, relative to each other (left). A panel image from the MIT300 dataset (right). The saliency map predictions given the panel as an input image. The maximum response

of each saliency model on each subimage is visualized (as an importance matrix). AUC and NSS scores are also computed for these saliency maps. The panel ranking is a measure of the correlation of values in the ground truth and predicted importance matrices (Figure from our work in Bylinskii et al. (2016)).

regions in a collection or in a panel (as in Fig. 9 to measure how well models predict the relative importance of image content), psychophysical patterns (pop-out search arrays and natural oddball scenes), as well as transformed images can be used to further differentiate among models.

- Collecting large scale data for constraining, training, and evaluating attention models is crucial to progress. Bruce et al. (2016) pointed out that the manner in which data is selected, ground truth is created, and prediction error is measured (e.g., loss function) is critical to model performance. Large scale click datasets (Huang et al. 2015; Kim et al. 2017) have been highly useful to train deep saliency models and to achieve high accuracy. However, clicks occasionally disagree with fixations. Thus, separating good clicks from noisy ones can improve model training. Moreover, studying discrepancies between mouse movements and eye movements, collecting new types of image and video data, as well as refining available datasets can be rewarding.

In this review, we examined the recent progress in saliency prediction and proposed several

avenues for future research. In spite of tremendous efforts and huge progress, there continues to be room for improvement in terms of finer-grained analysis of deep saliency models, evaluation measures, datasets, annotation methods, cognitive studies, and new applications.

Braided Electrodes

Simon F. Giszter, Taegyo Kim and Almut Branner
Neurobiology and Anatomy, Drexel University
College of Medicine and School of Biomedical
Engineering and Health Systems, Philadelphia,
PA, USA

Definition

Braided electrodes consist of multiple, independent fine wires that are braided around a stiff core or needle that is used to aid insertion.

Detailed Description

The braids are like a textile or fabric covering around a stiff core. This needlelike core is needed to shape the braid initially and can also be used as an aid for insertion into tissue. It is removed after insertion for chronic applications to allow the braid to move with the tissue and reduce its footprint in the tissue. Each wire in a braid is a separate conductor, i.e., microelectrode. These wires can be used for either recording or stimulation depending on the material used and the impedances of the active sites (Figs. 1 and 2).

Rationale for Braided Electrodes: Braided electrodes take advantage of two things: (a) the flexibility/compliance of ultrafine microwires and (b) the structure and strength of interwoven strands.

The stability of chronic electrode implants is influenced among other things by (a) the compliance, (b) the size, and (c) the biocompatibility and

coatings of the implanted structure (Branner et al. 2004; Hochberg et al. 2006; Misra et al. 2013). The compliance of a single wire scales as the cube of the length over radius to the fourth power (e.g., Head et al. 1989; Kim et al. 2013). This means that the degree of stress and strain in the tissue surrounding an implanted electrode is reduced as electrode wires become thinner and longer. The conductance of the rodlike electrode members will only reduce as a function of the second power of radius reductions, so conductance is not an issue as wires get thinner.

Fifty micron wires are routinely used to record neural activity. Given the relationships mentioned above, creating a neural interface of a collection of independent 10 μm wires will significantly improve the compliance of the ensemble and increase recording electrode density while potentially preserving wire conductance within the operating range of current and conventional headstages and amplifiers used in single-unit recording.

Mechanical Testing: Mechanical bending tests have shown that the implanted portion of braided microelectrodes consisting of either 12 or 24 ultra-fine wires (9.6 μm or 12.7 μm) had 4–21 times better mechanical compliance than a single 50 μm wire. The wired connections between an implant and a percutaneous connector also play a vital role in the long-term performance of an implant since these tethers can produce forces on the implant. The mechanical compliance of the bundles of ultrafine wires were 6–96 times better than the compliance of a single 50 μm wire (Kim et al. 2013).

Histology: Short Summary of Histology

Different Types of Braided Electrodes: Braids are made from various topologies of interwoven strands (Ko and colleagues, 4). The mechanical properties of precisely braided composites offer several advantages that are presently utilized in textiles and modern composite materials (e.g., various sports equipment and body armor). Examples of topologies for microelectrode braids are

Braided Electrodes, Fig. 1 Examples of braided electrode probe assemblies and springy flexibility of braided probes after core removal (From Kim et al. 2013 with permission)

Braided Electrodes, Fig. 2 Stages in braided probe insertion and deployment. (a) Assembly. (b) Insertion of assembly. (c) Removal of core leaving only braid. (d)

Remaining braid/tether probe after deployment (Reproduced from Kim et al. 2013, with permission)

(a) tubular braids, (b) 3D braids, and (c) figured braids:

- (a) Tubular braids form the simplest assemblies with symmetric repeating patterns. The recording sites are located at the ends of the wires which roughly puts them in a circular arrangement at a particular depth below the tissue surface.
- (b) 3D braids are similar to tubular braids as they consist of symmetric repeating patterns, but the recording sites for each wire in the braid are placed at varying locations throughout the braid. This allows a more distributed placement of recording sites in the tissue.

(c) Figured braids do not have a symmetric repeating pattern but have systematic alterations in the braid pattern through the structure to alter compliance or to assemble wires in specific groupings and to aid in the placement of recording sites along the braid.

Special Techniques Enabled by Braiding

Combinatorics

The two characteristics of combinatoric probes are that (a) each wire has multiple recording sites along its length and (b) the recording sites of different wires are organized in a patterned braid into unique combinations of electrodes such as

stereotrodes or multitrodes. Gerstein and Clark showed in 1964 that it was possible to record multiple classifiable single-unit action potentials from multiple 5–10 μm exposed recording points spaced along a single 10 μm Tungsten microelectrode (Gerstein and Clark 1964). We have also observed that two electrically connected electrodes in a Utah array can occasionally still record single units, but both channels record the same activity. Based on their results and our observations, and back-of-the-envelope calculations of theoretical electrical networks, signals from separate recording sites along one such electrode wire will roughly add (Fig. 3).

Under the assumption that most single-unit pickup near a spatial site will simultaneously co-occur on each of the wires that comprise the spatial site in a braid, a neuron in a combinatoric electrode will have a “signature.” That is, a unit can be spatially assigned based on the unique collection of wires on which it co-occurs. The combinatoric probe is thus an innovation that exploits principles

of stereotrode/tetrode methods (Gray et al. 1995) for multisite wires organized into a 3D combinatoric pattern. Because we know which electrodes picked up a particular event, cross-correlated patterns of recorded spikes can then be separated out into their location of origin on the probe in most instances. Some activity may remain spatially undefined in cases of limited (thus ambiguous) pickup. The improved yield of units in a combinatoric arrangement of n wires arranged in groups of k recording points per spatial site from combinations of recording points on multi-recording-point wires can potentially be huge.

$$nC_k \text{ or } \binom{n}{k} = \frac{n(n-1) \dots (n-k+1)}{k(k-1) \dots 1},$$

ie, $\frac{n!}{k!(n-k)!}$

The yield improvement arises from the process of arranging recording points on wires into many

Braided Electrodes, Fig. 3 Combinatorics concept examples. (a) A “4 choose 2” combinatorics probe with two recording points per wire, and six spatial location sites

AB, BC, CD, AC, AD, and BD. (b) A “4 choose 3” combinatorics probe with three recording points per wire, and four spatial location sites ABC, BCD, ACD, and ABD

or all of the possible combinations at spatial sites. For example, in Fig. 3a, we show four wires with four recording points each. In Fig. 3a, we obtain ${}_4C_2$ spatial sites ($4 \text{ choose } 2$) = 6 stereotrode sites. In Fig. 3b, we employ four wires, each with three recording points, used in triode groupings, and obtain ${}_4C_3$ ($4 \text{ choose } 3$) = 4 triode sites, compared to a single tetrode site. Accordingly, a braid of six wires allows ${}_6C_4$ spatial sites, which gives 15 tetrode sites, composed using only six multisite wires, each wire with ten recording points.

For this recording strategy to provide unambiguous unit data the firing must ideally be sparse, largely desynchronized on a millisecond time scale, and loss of data or spatial precision due to occasional collisions must be acceptable for the use and algorithms applied to recorded data. One determining factor for collision likelihood is the number of recording points per wire. A 24-count braid organized as tetrodes allows up to ${}_{24}C_4$, i.e., 42,504 uniquely coded spatial sites. The collision likelihood per wire in the probe with sufficient recording points to fully span the potential 42,504 separate spatial sites would clearly be unacceptably large. In contrast the number of spatial sites that are possible using 4–6 recording points per wire would still be an improvement compared with current conventional designs, while the likelihood of the collisions on a wire would probably be acceptable. For example, settling on limiting the design to only four recording points per wire allows 24 spatially separate tetrodes to be very simply constructed within the 24-wire tubular braid, allowing ~4 times the unit yield per wire compared with using six separate tetrodes. Optimized recording arrangements in this combinatoric design space will thus depend on the neural density, average firing frequency, and spatial firing pattern statistics and the collision tolerance of the applications and analysis algorithms using the data.

Brain Architecture Management System (BAMS)

Mihail Bota

Department of Biological Sciences, University of Southern California, Los Angeles, CA, USA

Definition

The Brain Architecture Management System (BAMS; <http://brancusi.usc.edu>) is an online publicly accessible neuroinformatic platform designed to handle neurobiological information at different organization levels of the vertebrate central nervous system (CNS).

Detailed Description

BAMS Structure

The backend database of BAMS is implemented in the latest MySQL public version, MariaDB (<http://mariadb.org>). The backend structure of BAMS is modular, with the *Brain Parts* module

as the center of the system. Any brain part (gray matter regions, fiber tracts, and ventricles) are uniquely defined in BAMS by a tuple made of its name, the nomenclature used to identify and name it, the nomenclature version, and species. A neuroanatomical nomenclature is defined here as an internally consistent set of terms used to name a CNS part. The number of terms included in a nomenclature is variable (at least one), and the nomenclature version uniquely specifies the set. Usually, a brain nomenclature is associated with a neuroanatomical atlas, but this does not constitute a constraint for inserting it. The constraints that are considered are the internal consistency, whether the reference is original research, and the brain region names are associated with textual definitions, or at least depicted on a brain atlas (Bota and Swanson 2005).

The BAMS modules are *Connections*, *Relations*, *Cells*, and *Molecules*. The *Connections* module holds data and metadata about macroscopic neuroanatomical projections between gray matter regions. Any neuroanatomical connection is represented in BAMS by a set of more than 40 attributes (Bota et al. 2005). The *Relations* module stores qualitative (topological) spatial relations between brain regions in the same species and defined in different nomenclatures, as well as the supporting references as metadata. The *Cells* module allows insertion of names and definitions of neuron types and classes, as well as relations between them, as collated from the published literature. It records neuronal population attributes, such as topographical positions within brain regions, densities, and patterns of staining. It also includes a classification schema, which allows specification of criteria used to hierarchically organize neuron nomenclatures (Bota and Swanson 2007). Thus, the *Cells* module allows insertion of different neuronal nomenclatures, hierarchically organized. A unique feature of this module is the set of classification criteria that can be associated to any hierarchically organized neuron nomenclature (“is-a” relationship). BAMS includes more than 100 structural, hodological (inputs and outputs), electrophysiological, and functional criteria and sub-criteria, which can be used to specify the common features

and specific differences of neuronal classes and types (Bota and Swanson 2007). Any neuronal class or type captured in a hierarchically organized manner includes the specific sets of criteria, as well as the relevant metadata (textual definitions, associated references, and collators names).

The *Molecules* module represents data and metadata as collated from the literature and pertaining to brain regions or neurons that are recorded in two general classes of physiological states of the animals (subjects): “normal” and “manipulatedQ” Molecules are also classified in two general classes: “cell associated” and “releasable by neurons.” The “cell associated” class is further divided in classes accepted by the IUPHAR nomenclature (<http://www.iuphar-db.org/index.jsp>).

The *Molecules* module allows insertion of quantitative and qualitative attributes of molecules identified using the most used techniques used in neuroanatomy: radioactive tracers, immunohistochemistry, and expression of genes at the regional and neuronal levels. It also includes a comprehensive schema for metadata representation of experiments, from the details of the used antibodies to the plane of sectioning. This metadata schema allows insertion of data and metadata specific to each of the used techniques listed above. A full description of this module can be found in Bota and Swanson (2006).

BAMS Interfaces and Inference Engines

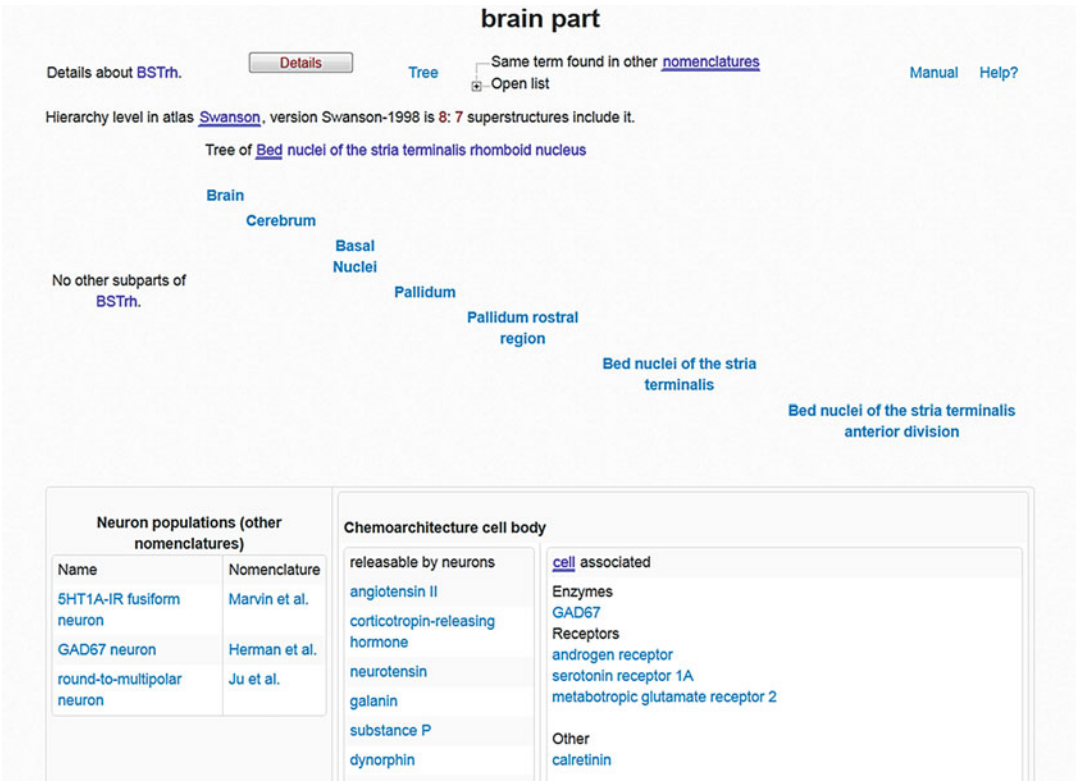

The Web BAMS interfaces are comprehensive and versatile, allowing users to search for information and manipulate inserted data and metadata in different way. Both interfaces and inference engines are implemented in PHP (<http://www.php.net/>), as well as JavaScript. The middleware PHP is continuously updated and upgraded, and at present we use its 5.5.x version. Generally, the outputs of searches are either text, tables, and images (PNG format). Each BAMS module described in the previous section can be searched for information in a different way. A complete description of search engines implemented in BAMS, as well as examples, can be found in its

Manual: http://brancusi.usc.edu/public/files/user_manual.pdf.

Two of the simplest ways to search for information in BAMS are by gray matter regions names and abbreviations. The results of these searches will be lists of regions with those names or abbreviations, respectively, which best match the searched strings. These lists are ordered in descending order of the relevance, as well as by the type of information that is associated in the system. Clicking on any of the retrieved results (gray matter regions names) will return the region information, recorded in BAMS, and links to the associated neurons, expressed molecules, and to its inputs and outputs (Fig. 1).

BAMS users have several options to create gray matter networks. First, they can use the input and output interfaces, choosing a certain set of regions of interest (Bota et al. 2005). The

connections between these regions will be first displayed in tabular formats. The interface that displays these tables of connections includes a link for extension of the networks with one more layer. Users will be asked to choose the regions of interest that are the targets of the afferent regions of the initial tables. Once this action is finished, the user-chosen networks will be displayed as extended tables, as well as in graphical formats. Examples of such complex networks that can be constructed by users can be found in BAMS' Manual and at the URL: <http://tinyurl.com/mf4jxws>. A second option to create gray matter regions networks is automated, and the users have to specify the first and the last region, as well as the number of intermediary layers (Bota et al. 2003, 2005). This engine infers all possible networks between the user-specified regions and with the preset number of layers (intermediary

Brain Architecture Management System (BAMS), Fig. 1 The general output of search for brain regions in BAMS. See text for details

stations), from the connections data inserted in BAMS. To reduce the number of possible networks, this engine constructs only the forward ones and with at least moderate connections. The third and the newest way to construct and visualize networks uses a graphical interface constructed de novo in the second generation of BAMS, BAMS2 (see below). This functionality can be accessed from the “Connectome” tab of BAMS’ *Menu*. The networks that can be accessed by users are those that can be constructed using the rat Swanson-2004 neuroanatomical

nomenclature and hierarchy (Swanson 2004) and “custom” matrices, created by the curators of the system. The first set of networks is those of the major divisions of the rat CNS. An example of such network is shown in Fig. 2.

Additionally, users can search for connections of regions, using autocomplete forms that allow both names and abbreviations. These forms are implemented in BAMS2 (see below).

The *Molecules* module data and metadata can be accessed in two ways: a simple browse function of molecules by categories and an engine that

Brain Architecture Management System (BAMS), Fig. 2 The network representation of connections of the rat somato-motor cortex, as defined in the Swanson-2004

nomenclature (Swanson 2004), constructed automatically in BAMS

compares the experiments inserted in BAMS. BAMS includes both presence and absence of molecules in brain regions or neuron; therefore, this variable will be always showed. The state of the animal, “normal” or “manipulated,” is also always associated with each record. BAMS includes an additional function that of inference of the expression patterns of gray matter parts that include subparts, and these are associated with molecules data and metadata. A complete description of the *Molecules* module and its interfaces can be found in Bota and Swanson (2006).

The *Cells* module interfaces include a simple browsing function, which lists the names of neurons, the associated neuron nomenclature, their definitions, and the collators’ names. It also includes search forms by names of neurons and by brain regions. The former is divided in “BAMS Reference” and “Other.” The names of neurons tagged with “BAMS Reference” are the standard terms of the system, while those tagged “Others” are synonyms or partial correspondences. The criteria for choosing a neuron name as “BAMS Reference” are described and discussed in detail in Bota and Swanson (2007).

Additional search functionalities include those for references inserted in BAMS and search for brain regions by species and for relations between brain parts defined in different nomenclatures.

BAMS2

In 2010 we decided to upgrade BAMS to the second generation. Thus, we constructed de novo the entire infrastructure, structure, and interfaces of the new system, BAMS2.

BAMS2 uses both PostgreSQL as a classic relational database and RDF triples to store the data and metadata. The Web framework Django is used to create its interfaces. BAMS2 (<http://brancusi1.usc.edu>) is not a simple iteration of the older system, because it includes new functionalities, besides the ones already existent in BAMS. Secondly, the BAMS2 public data and metadata is encoded in RDF triplets and queried using

SparQL. Finally, we developed in BAMS2 a comprehensive and versatile *Personal Workspace* module, which allows rapid insertion of connections data annotated and collated directly from experiments. The *Workspace* data and metadata are stored in PostgreSQL relational database. Besides its extended functionality to handle and represent neuroanatomical data directly inserted by neuroanatomists, the *Workspace* also allows third-party systems anonymous access, to create tabular and graphical representations of their stored connections data. This novel functionality of BAMS2 Workspace is exemplified to date in the “Connectome” tab of the classical BAMS (see above).

BAMS: Inserted Information

BAMS includes to date about 1.25 million details, most of them manually inserted. It stores about 10,000 CNS parts in five species and 33 nomenclatures; about 70,000 connections reports, mostly in the rat CNS; 341 neuron identified names identified in more than 200 rat regions; and about 9000 molecule reports in both rat and mouse CNS and related to more than 100 molecules expressed in these species brains. These data and metadata have been collated from more than 700 published references, most of them original research articles.

Definition

An atlas is a collection of maps. Used in a geographic sense, an atlas refers to a collection of maps of an entire planetary body such as that of the Earth or the Mars. In an analogous manner, brain atlases are collections of brain image data where each collection typically spans across one (or more) whole brain. This article primarily provides pointers to other articles dealing with brain atlases. See the Cross-References/Related Terms below.

Brain Energy Metabolism

Daniela Calvetti and Erkki Somersalo
Department of Mathematics, Applied
Mathematics, and Statistics, Case Western
Reserve University, Cleveland, OH, USA

Definition

The brain is an organ of great complexity, whose mystique is tightly guarded by several protecting layers, from the physical armor of the skull to the biochemical border of the blood–brain barrier. What fuels the brain to sustain a range of neurophysiological states is a question of great importance not only to advance our insight on how brain functions, but also to shed some light on how to treat patients with neurological and psychiatric conditions.

The electrophysiological activity of the brain, usually measured in terms of frequency of neuronal firing, is a process which cannot be sustained unless the underlying metabolism is able to provide the energy required for the process of depolarization and subsequent repolarization to take place, including the supporting role of glial cells. In this chapter, we give an overview of the modeling of brain energy metabolism and how it can be coupled to models for electrophysiological and cerebrovascular dynamics.

Our understanding of the brain keeps evolving, so no assumption about brain energy metabolism should be taken for granted, and even the fundamental roles of the different cell types keep being reassessed. For example, in the studies on energetic substrates other than glucose, astrocytes have emerged as playing a much more prominent role than originally thought. How fundamental glial cells are for brain electrophysiology and what portion of the energetic needs must be allocated for astrocytes' functions continues to be a topic of active research. Due to the limited volume inside the skull and the lack of myoglobin, brain metabolism depends crucially on the cerebral

blood flow for the delivery of glucose and oxygen, the principal substrates for energy production, and the removal of carbon dioxide, lactate, and other byproducts of the metabolism.

Cerebral hemodynamics has its share of open questions. Already in the nineteenth century, the physiologist Angelo Mosso measured a localized increase in blood flow following sustained neuronal activation, a phenomenon with numerous details for which several potential explanations have been proposed but still waiting to be fully settled. For example, a discovery three decades ago, the physiological uncoupling of cerebral blood flow and oxidative metabolism during somatosensory stimulation has raised the question of what the reasons may be for the significant oversupply of oxygenated blood in activated brain regions. All these questions are tied to electrophysiology through metabolism, underlying its pivotal role in the process of integrating the different scales of the multiscale brain.

Detailed Description

The Energetic Cost of Brain

Electrophysiological Activity: Discoveries and Mysteries

Beyond the Naked Neuron: The Role of Astroglia
Traditionally, computational neuroscience has focused on a single neuron, or more generally, a network of neurons. From early on, however, experiments have verified that the behavior of neurons is strongly conditioned on the environment, and in particular, by the concentration of electrolytes in the surrounding environment: for example, it is well understood that a rise in extracellular potassium concentration triggers seizure like firing or bursting in neurons. This suggests that to understand how brain functions, it is necessary to go beyond the naked neurons to design models that take into account the regulatory factors of the environment and their interaction with neurons. In brain tissue, astroglia is the main regulator of the neuron's electrolytic environment, and the interplay between neurons and astrocytes with regard to energy metabolism is key for the glutamate–glutamine cycling between

the presynaptic neurons and astrocytes. The changed perception of astroglia in the past decades has been very dramatic, as they have gone from merely space filling connective tissue (The Greek meaning of glia is glue, revealing rather openly the initial impression) to being *the other brain* (Volterra and Meldolesi 2005; Fields 2009; Dienel 2017; Bak et al. 2018).

Cerebral Metabolism in Health and Disease

The brain is the most metabolically demanding organ in the human body: While an adult brain constitutes typically only approximately 2% of the total body weight, it accounts for approximately 20% of total oxygen consumption and 25% of total glucose consumption at awake resting state (Sokoloff 1999; McKenna et al. 2012). The complexity of the biochemistry of the brain and the difficulty in accessing this organ without major disruption in its functions contribute to the challenge of understanding cerebral metabolism. The price to be paid for the protection provided by the skull is that brain has no space to store any significant amount of energetic fuel to resort to in case of disruption in the blood flow, and the lack of myoglobin means that essentially all oxygen available to the brain must be provided through the cerebral blood flow. At resting state, most energetic needs of the brain go towards keeping the neuronal membrane potential at about -70 mV; these needs are met by the coordinated action of hemodynamics and metabolism. During neuronal activation, when additional energy is needed to ensure that the depolarized membranes return to the resting voltage, the cerebral blood flow increases to sustain the increased cerebral metabolic rate in a highly coordinated manner. Therefore, it should not come as a surprise that even a small perturbation of cerebral metabolism or hemodynamics will result in major disruption of the brain activity.

In recent years, there has been an increasing interest in understanding the underlying metabolic disruptions behind neurodegenerative disorders to direct the search for better pharmaceutical therapies and to suggest life style changes. While many neurodegenerative conditions may have a genetic basis, metabolic changes often occur before the onset of the disease, hence suggesting

that trying to return the metabolism to its healthy state may be a way to delay, if not offset, the disease. Given the brain's primary need for energy to sustain the membrane polarization, many diseases resulting in brain degeneration are associated with perturbations of the energy metabolism, affecting either the glucose metabolism or the processes leading to oxidative phosphorylation, a process responsible for ATP production in bulk.

Among today's aging population, Alzheimer's disease (AD) is one of the most prevalent and devastating age-related neurodegenerative conditions, affecting the ability to create new memories and to tend to even the most basic tasks. While the etiology is still for the most part elusive, impairment of glucose metabolism is such an invariant pathophysiological feature of AD to suggest that the consequences of glucose hypometabolism lead to neuronal degeneration and cognitive deficits (Chen and Zhong 2013). Because the occurrence of impairment of glucose metabolism in AD may precede the onset of cognitive dysfunctions by years (Cunnane et al. 2011), it may be considered part of the AD biomarker. Positron emission tomography (PET) studies using ^{18}F fluorodeoxyglucose (FDG) in AD patients during disease progression have shown that the severity of the symptoms correlates with the reduction of glucose metabolism in the parieto-temporal lobe, the posterior cingulate cortex, and the frontal areas, while the primary visual and motor cortex, the cerebellum, the thalamic and basal ganglia nuclei are less affected (Mosconi 2005); at first, the reduction in glucose metabolism arises in memory-related regions like the hippocampus and the entorhinal cortex. This is confirmed in Melrose et al. (2011) where it was shown that AD patients with hypometabolism suffer greater impairment in the right hemisphere, in particular in the frontal pole, the dorsolateral prefrontal cortex, the superior parietal lobule, the inferior parietal lobule, and the posterior superior and middle temporal gyri.

Cognitive deficits are a challenge for insulin-resistant type 2 diabetes mellitus patients, who are at increased risk of AD; vice versa, most AD patients show insulin resistance, hence prompting some researchers to label AD as *type 3 diabetes mellitus*, or brain insulin resistance. Incidentally, GLUT4, the glucose transporter into

hippocampus neuron, is insulin responsive (Apelt et al. 1999). The final steps of the metabolism of glucose occur in mitochondria where the glucose products enter the Krebs cycle to provide the substrates for oxidative phosphorylation producing the majority of ATP. Disruption in either of these pathways will interfere with complete glucose metabolism, in turn rendering the cell unable to provide the ATP required to meet the energy demands, with the result that the neuron may undergo apoptosis (Shoffner 1997). Deposition of β -amyloid in mitochondria contributes to the disruption of oxidative phosphorylation in mitochondria. In a chicken or the egg type of argument, lower neuronal activity in turn would decrease glucose metabolism, hence worsening the symptoms of AD. In a phase I trial, continuous deep brain stimulation of the fornix for one month triggered a local increase in glucose metabolism (Smith et al. 2012).

Epilepsy is another major neurological disease with known connections to metabolism. The generation of seizures is likely to be facilitated by deficient energy production leading to destabilization of membrane potential. Traditional anti-seizure drugs overcome the destabilization of membrane potential by sedation, i.e., inhibiting action potential transmission: This curbing of the energy demand may cause cognitive deficits and other unpleasant side effects. It has been known since the time of Hippocrates (Wheless 2008) that fasting can be used to treat epilepsy. A less drastic way to make the body produce acetone and beta-hydroxybutyric acid is to follow a diet rich in fat and poor of carbohydrates, usually referred to as ketogenic diet. The use of ketogenic diets to control epilepsy has been typically limited to pediatric epilepsy patients (Martin et al. 2006): Ketone bodies enter the Krebs cycle anaplerotically and are oxidized by the brain. Diets based on medium chain triglycerides replenishing the Krebs cycle anaplerotically have been shown to have anticonvulsant action without the heavy side effects of traditional drugs. A recent review (McDonalds et al. 2018) provides an overview of the known mechanisms perturbing oxidative glucose metabolism in epilepsy and discusses the benefits of a dietary regimes based on medium chain triglycerides in chronic epilepsy. If glucose metabolism is

unable to meet the highly increased energetic demand during seizure, the compensation mechanisms initiated by the brain in an attempt to increase ATP production may impair oxidative phosphorylation due to oxidative stress. The explanation of the effectiveness of the dietary changes requires a solid understanding of the brain cell metabolism.

The decrease in glucose and oxygen metabolism of brain cells, which is part of the normal aging process, becomes critical in the onset and progression of amyotrophic lateral sclerosis (ALS), Parkinson's (PD), and Huntington's (HD) diseases (Hoyer 1982). As is the case for AD, FDG-PET studies show a reduced glucose utilization in specific brain regions of PD, ALS, and HD patients; changes in blood-brain barrier and lower expression of glucose and monocarboxylate transporters have been found in patients with cognitive impairments; see, e.g., Camandola and Mattson (2017). In PD patients, the glucose hypometabolism may be caused by an alteration of an enzyme in the Pentose Phosphate Pathway (PPP) induced by environmental toxins (Lei et al. 2014). A deeper understanding of the metabolic disruption in the brain of PD patients may guide interventions to ameliorate the associated neuropathology and motor deficits.

ASL patients experience increased energy expenditure at rest (Funalot et al. 2009) and have been reported to suffer from multiple metabolic perturbations, including glucose intolerance, insulin resistance, high levels of fats in blood, as well as astrocyte end feet degeneration, suggesting that altered metabolism plays a significant role in ALS progression.

In HD, where early degeneration of neurons in the striatum results in involuntary motor movements, a decrease in striatum metabolism occurs well before the atrophy, and glucose hypometabolism is strongly correlated with the progression of the disease. Early stage HD patients have normal levels of glucose transporters but lower than normal glucose uptake. As in other neurodegenerative conditions, while the picture of the associated metabolic disruptions is not clear, intervention to boost neuroenergetics may

delay the onset or slow the progression of the disease.

Cortical spreading depression (CSD) occurring usually with migraine, stroke, and brain trauma (Lauritzen et al. 2011) is characterized by a failure of brain ion homeostasis: An increase of extracellular potassium leads to depolarization of the brain cells and increased extracellular glutamate concentration by an impaired glutamate uptake by astrocytes. The energetic need increases beyond the supply of glucose and oxygen, possibly because of a failure in the neurovascular signaling that normally would lead to hyperemia. A detailed picture of the chain of events during CSD, and in particular the causal sequence between electrophysiological activity, metabolism, and neurovascular signaling are topics of active study, underlining the importance of mathematical modeling and simulation.

Energy Metabolism from Top Down

This section contains a general overview of the brain energy metabolism. For a classic text on the topic, we refer to Siesjo (1978); see also Lajtha (2007). The energy supply of the brain is for the most part a product of the aerobic metabolism of glucose, whose complete oxidation process can be expressed as

How completely the glucose entering brain tissue is oxidized can be expressed as the ratio of the cerebral metabolic rates, intended as the brain molar uptake, of glucose and oxygen, CMR_{glc} and CMR_{O_2} , or oxygen-glucose index (OGI) of the brain,

$$\text{OGI} = \frac{\text{CMR}_{\text{O}_2}}{\text{CMR}_{\text{glc}}}.$$

If all glucose entering the brain undergo complete oxidation, it follows from the stoichiometry that $\text{OGI} = 6$. In normal conditions, however, the typical observed OGI is of the order 5.2–5.4 with spatial and temporal variation (Vaishnavi et al. 2010), indicating that a small portion of the glucose undergoes a nonoxidative process, resulting

in the production of lactate (or lactic acid), the end product of anaerobic metabolism of glucose,

Therefore, the complete metabolic fate of glucose can be described in terms of these two processes, summarized by OGI,

where Glc and Lac denote glucose and lactate, respectively.

To understand what controls the OGI, we need to look at the metabolism of brain cells accounting separately for cytosol and mitochondria.

The most prominent cytosolic pathway in most living cells is glycolysis, a complex chain of enzymatic reactions converting glucose into pyruvate or lactate. Lumping a number of the detailed reactions together, we can break down glycolysis into two simplified steps,

where ATP and ADP denote adenosine triphosphate and adenosine diphosphate, respectively, NAD^+ denotes nicotinamide adenine dinucleotide, and NADH its reduced form, whose relevance for energy metabolism will be discussed later. ATP can be thought of as the energy currency, because the cleaving of one of its three phosphate groups provides energy for reactions or transports that would not otherwise take place. More specifically,

where P_i is an inorganic phosphate group, not accounted for in our lumped glycolysis description. If we lump further the reactions in glycolysis into the breakdown of glucose to lactate,

we see that glycolysis can produce energy in the amount of two moles of ATP per mole of glucose in an anaerobic fashion.

Before introducing oxidative metabolism, we point out that in the second step (2) of glycolysis, the role of NADH, nature's reducing agent, is to donate electrons needed for the reaction and become NAD^+ ,

Conversely, the electrons freed when the reaction occurs in the reverse direction are absorbed by the oxidizing agent NAD^+ , which turns into NADH,

In Eq. (2), pyruvate is reduced to lactate in a reaction facilitated by the enzyme lactate dehydrogenase (LDH). Since this reaction is reversible, the same enzyme catalyzes the oxidation of lactate to pyruvate, with the direction of the reaction depending, among other things, on the ratio of the concentrations of lactate and pyruvate; in normal condition, the equilibrium is towards lactate in a 10:1 ratio and is in near equilibrium with the ratio of NADH/NAD^+ (Mintun et al. 2004).

Glycolysis alone is not sufficiently effective to provide the energy needed by the brain, as can be seen from the following simple calculation. The brain consumes about 20% of the total energy of the human body, which, assuming a total energy consumption of 2000 kcal per day, amounts to 1680 kJ per day, the equivalent of about 20 Watts. If this energy were to come from glycolysis alone, about 27.5 moles of glucose would be required: This, with the molar mass of approximately 180 g per mole, would amount to about 5 kg! A much more efficient mode of energy production is through mitochondrial oxidative phosphorylation.

Pyruvate, a pivotal substance in energy metabolism, is produced in cytosol either from the processing of glucose (Eq. 1) or, occasionally,

through oxidation of lactate. Pyruvate entering the mitochondrial matrix feeds a complex chain of reactions, known as the tricarboxylic acid (TCA) cycle, or Krebs cycle, which strips the carbons from pyruvate and produces NADH. From the point of view of NADH production, the Krebs cycle can be summarized approximately by the lumped reaction

emphasizing the fact that each pyruvate molecule produces five reducing equivalents inside the mitochondrion. In the presence of oxygen, reducing equivalents, i.e., NADH, become a great source of energy. A complex process, known as oxidative phosphorylation (OxPhos), taking place in the mitochondrial matrix, binds energy into ATP according to the approximate stoichiometry

In summary, following glucose from the beginning of glycolysis, into the TCA cycle to the end of oxidative phosphorylation, shows that through aerobic metabolism we have

that is, 17 times more ATP per glucose is produced compared to anaerobic metabolism. This means that to satisfy the 20 Watt energy consumption of the brain, only about 300 g of glucose per day suffices.

Since ATP is produced in mitochondria, while most energy demand is for processes occurring in cytosol, there must be a way for ATP to be transferred from mitochondria to cytosol, as described in Klingenberg (1980) and Kunji et al. (2016). Only selected molecules can cross the mitochondrial membrane, which is impermeable, for example, to NADH and NAD^+ , important players in the coupling of glycolysis and

oxidative phosphorylation. The virtual movement of NAD^+ and NADH across the mitochondrial membrane is effected by the malate–aspartate shuttle (MAS), schematically summarized in Fig. 1, involving several metabolites (Lajtha 2007).

The balance of NADH and NAD^+ is crucial for cell functions. As NADH produced in the first part of glycolysis enters mitochondrion to participate in oxidative phosphorylation, the redox balance in cytosol shifts towards NAD^+ and lactate production in cytosol stops, hence decreasing the rate of anaerobic oxidation. On the other hand, if lack of oxygen stops oxidative phosphorylation, the slowing down of malate–aspartate shuttle triggers pyruvate reduction (Eq. 2) to lactate, increasing the rate of anaerobic metabolism (Mintun et al. 2004). While the basic control mechanism is well understood, indirect effects complicate the picture: The reactions (3) and (4) affect the pH of the environment, a factor that regulates several of the enzymes involved in the energy metabolism of the cell. Also, the MAS involves metabolites of the TCA pool, hence indirectly affecting the metabolic process in the mitochondrion. These observations underline the difficulty of building a reliable and comprehensive computational model that takes into account the fine details and feedback mechanisms that eventually regulate the balance between aerobic and anaerobic metabolism.

We conclude by pointing out that a lot of the communication between a cell and the surrounding environment is through the cross-membrane exchange of biochemical species. Some of the exchanged substances, e.g., gases, have been assumed to diffuse passively according to cross-membrane concentration gradients, while other molecules, most notably glucose and lactate, require the help of specific transporter proteins, e.g., glucose transport protein (GLUT) and monocarboxylate transport protein (MCT), both expressed in different isoforms. Thus, a dynamical system describing the metabolic processes in the cell is a complex nonlinear system with proper models for enzymatic reactions and passive and active transporters, as discussed in more detail later.

Brain Energy Metabolism, Fig. 1 The malate–aspartate shuttle, a mechanism whose net effects is equivalent to a NADH/NAD^+ exchange across the inner membrane of the mitochondrion (vertical line) that is impermeable to these cofactors. The shuttle depends on two membrane-bound proteins, the malate- α -ketoglutarate antiporter, and the aspartate–glutamate antiporter. The key MAS enzyme,

malate dehydrogenase (MDH), acts differently in cytosol and in mitochondrion by facilitating the reactions $\text{Mal} + \text{NAD}^+ \rightarrow \text{OAA} + \text{NADH}$ in the latter, and the reverse reaction in the former. Observe that the net effect is purely on the redox both sides of the membrane. Abbreviations: α -ketoglutarate (AKG), aspartate (Asp), glutamate (Glu), malate (MAL), oxaloacetate (OAA)

Zooming In: Neurons and Astrocytes

The description above makes no distinction between the metabolic processes in neuron and astrocyte. However, since these cell types have different roles in the signal processing of the brain, it is reasonable to expect differences in their metabolism also. Indeed, while many of the reaction chains can be found in both neuron and astrocyte, the enzymes and the cross-membrane transporters may have different concentrations and can be of different isoforms, and the regulatory factors in the two cell types may vary. In addition, the mitochondrial density in neuron and astrocyte is different and may even vary from one part of the cell to another. Moreover, neurons and astrocytes have different spatial configuration and geometry; hence, the surface areas are different. In fact, the role of the astrocytic end feet wrapped around the capillaries continues to be a topic of active research. In the light of these considerations, even

if the two cell types have for the most part the same reactions and transfers, we cannot assume that the reaction and transport rates are the same.

The V-Cycle: Glutamate–Glutamine Cycling The neuronal signal carried by the action potential propagates from presynaptic neuron to the postsynaptic neuron through a process which includes chemical signaling using excitatory neurotransmitters, whereas inhibitory neurotransmitters can stop the action potential propagation. The most common excitatory transmitter in brain, but not the only one, is glutamate, while γ -aminobutyric acid (GABA) is most commonly responsible for the inhibition of an action potential. We start by addressing the role of glutamate.

As the action potential reaches the end of an axon, the reversed membrane voltage potential causes the calcium channels to open, triggering a massive release of glutamate (Glu) into the synaptic cleft. The glutamate receptors in the dendrite of

the post-synaptic neuron sense the increased glutamate concentration, causing an opening of sodium channels and a triggering of an action potential that continues to travel down the dendrite. As long as the glutamate concentration remains significant in the cleft, the sodium channels remain open, so it is imperative that the transmitter is promptly removed from the cleft. Glutamate cleaning is done mostly by astrocytes (Anderson and Swanson 2000): After the uptake, the glutamate is amidated to glutamine (Gln) in the cytosol of the astrocyte by the astrocyte-specific enzyme glutamate synthetase (GS) according to the stoichiometry

Glutamine is not excitatory and therefore can be returned to the presynaptic neuron without causing a trigger of action potential. In neuron, upon the cleaving of an ammonium, glutamine

becomes glutamate as the end product of the reaction

catalyzed by the phosphate-activated glutaminase (PAG) enzyme, believed to be located at the inner membrane of neuronal mitochondrion. A cartoon of the signal transmission and glutamate cycling for glutamatergic neuron is shown in Fig. 2.

The presence of GABA in the synaptic cleft inhibits the opening of the sodium channels, thus effectively stopping the action potential transmission. The fate of GABA parallels in many ways that of glutamate. After having been released into the synaptic cleft by GABAergic neurons, it is taken up by astrocytes and eventually returned to GABAergic neurons in the form of glutamine: Overall, the GABA cycle is more complex than the glutamate–glutamine cycle. GABA is

Brain Energy Metabolism, Fig. 2 Meeting at the synaptic cleft of glutamatergic neuron and astrocyte. Glutamate in presynaptic neuron is packed in vesicles that merge with the axon membrane, releasing the glutamate into the

synaptic cleft. The glutamate is immediately taken up by the astrocyte that amidates it to glutamine, a neutral substance from the point of view of neurotransmission, and can be safely diffused back to the presynaptic neuron

synthesized from glutamate by the glutamic acid decarboxylation (GAD) enzyme, present in different isoforms both in neuron and astrocyte.

A schematics of the neurotransmitter cycling in the context of an excitatory (top) and inhibitory (bottom) event is shown in Fig. 3.

B

Brain Energy Metabolism, Fig. 3 Schematic picture of the glutamate–glutamine–GABA cycling between neurons and astrocytes. (Top) Glutamatergic neuron and astrocyte with the glutamate–glutamine cycle, also known as V-cycle. (Bottom) GABAergic inhibitory neuron and

astrocyte. The figures indicate the main coupling sites with the metabolic processes, and in particular, the TCA cycle in mitochondria. The abbreviations are succinate (Suc), α -ketoglutarate (AKG), malate (Mal), oxaloacetate (OAA)

The glutamate–glutamine cycle and the GABA–glutamate cycle between neurons and astrocytes are only a part of the full picture of reactions involving glutamate that participates in the metabolic processes, including the malate–aspartate shuttle (Hertz and Chen 2017). Due to space limitation, we omit many details, some of which have not been fully resolved yet and continue to be the topic of active investigation, for example, the mechanisms by which the ammonium is returned from neuron to astrocyte (Cooper 2012; Calvetti and Somersalo 2013).

In presynaptic glutamatergic neurons, glutamate is packed into vesicles that in connection with the axonal action potential transmission merge with the cell membrane and lead to glutamate release. The articles (Attwell and Laughlin 2001; Howarth et al. 2012) contain a careful analysis of the energetic cost of glutamine–glutamate cycling. The estimated cost in astrocyte is approximately 2.33 ATP, with 1.33 for the uptake and 1 for the processing. The energetic cost of vesicle packing in neuron is only 0.33 ATP per glutamate molecule. The real cost incurred by the signaling takes place in the postsynaptic neuron: Each vesicle contains about 4000 glutamate molecules, and the release of one glutamate vesicle leads to the entry of 210 000 Na^+ ions in the postsynaptic neuron, which triggers also the signal in the dendrite traveling down towards the soma, all this requiring ATP to restore the membrane potential, as discussed below.

Transmembrane Ion Transport and Signal Propagation The most significant demand for ATP generated in neurons is for the ion pump action necessary to restore the membrane potential during signal propagation. It is well understood that the signal propagation along the neuronal cell membrane includes a process by which extracellular sodium enters the neuron (depolarization), followed by the outflow of intracellular potassium (repolarization), as accurately described by the classical Hodgkin–Huxley model (Keener and Sneyd 2009).

The major engine for the restoration of the membrane potential, which requires the

concurrent extrusion of excess sodium from the cell and intake of potassium, is the sodium–potassium pump, or Na^+/K^+ -ATPase, a protein in the plasma membrane that moves the ions against the concentration gradient by utilizing the energy released by the dephosphorylation of ATP. Denoting by K_e^+ and K_i^+ the extracellular and intracellular potassium, respectively, and using a similar notation for sodium ions, the pump action can be expressed as

A schematic of the mechanism of the pumps is shown in Fig. 4.

Computational Models

The metabolism in neuron–astrocyte complex is usually described in terms of well-mixed homogenized multicompartment models. Well mixed means that within a compartment, every metabolite change is observed everywhere without a delay, implying restrictions on the size scale of the model. The number of compartments included in the model depends on the desired level of detail. Neuron, astrocyte, and extracellular space (ECS) are usually accounted for as separate compartments in models of cerebral cellular metabolism, as is blood, needed to replenish the supply of metabolites. In complex models of brain energy metabolism, the neuron and astrocyte are separated into cytosolic and mitochondrial subcompartments. For an overview of the current models in literature, we refer to Somersalo et al. (2012).

We begin our overview of mathematical models of brain energy metabolism with an outline of the design principles of spatially lumped models. Assume that the model comprises L compartments. A *metabolic network* consists of biochemical reactions R_j and transports T_k between compartments: For each metabolic reaction R_j , a corresponding reaction flux φ_j is assigned and, likewise, each transport T_k is associated with a transport flux ψ_k . These quantities are typically expressed in units of $\mu\text{mol}/\text{min}$,

Brain Energy Metabolism, Fig. 4 The sodium–potassium pump action. With the energy released from the dephosphorylation of the ATP, the pump moves three sodium ions out of the neuron, replacing them with two

potassium ions, the ion movement being executed against the concentration gradients to reconstitute the transmembrane resting potential

scaled to correspond to one gram of brain tissue. The reaction and transport fluxes are arranged into vectors,

$$\varphi = \begin{bmatrix} \varphi_1 \\ \vdots \\ \varphi_n \end{bmatrix}, \quad \psi = \begin{bmatrix} \psi_1 \\ \vdots \\ \psi_m \end{bmatrix},$$

n and m being the number of reactions and transports included in the model, respectively.

Each reaction depletes some metabolites and produces others; likewise, each transport moves metabolites from a compartment to another. Since the role of the same metabolite may change from one compartment to another, we identify metabolites by their chemical composition and the corresponding compartment, so that, e.g., cytosolic glucose in neuron is regarded as different from the cytosolic glucose in astrocyte. Given the complete list of compartment specific metabolites, for each reaction R_j we define the stoichiometric vector $\mathbf{s}_j$ specifying how many molecules of each

metabolite, accounted for with its compartment affiliation included, is produced (positive entry) or consumed (negative entry) by the reaction. Similarly, a transport T_k moves a metabolite from one compartment to another, and we define the associated stoichiometric vector $\mathbf{s}_k$ indicating the number of metabolites depleted (negative entry), or replenished (positive entry). The stoichiometric vectors corresponding to all reactions and transports in the model can be stored as column vectors of the stoichiometric matrix,

$$S = [\mathbf{s}_1 \quad \mathbf{s}_2 \quad \dots \quad \mathbf{s}_N] \in \mathbb{R}^{M \times N},$$

where $N = n + m$ and M is the number of metabolites included in the model, counted with the multiplicity of compartments.

To set up a dynamical model, tracking the changes of the metabolites over a time period, the relative volumes, intended as percentages of the total volume, of the compartments need to be included. Assuming that the model domain is a

unit volume, let η_ℓ denote the volume fraction of the ℓ th compartment, $\eta_1 + \dots + \eta_L = 1$. We define the

volume matrix $V \in \mathbb{R}^{M \times M}$ as a diagonal matrix with

V_{jj} = volume fraction of the compartment assigned to the j th metabolite.

Thus, if the first metabolite in the list is astrocytic glucose, V_{11} is the volume fraction of astrocyte. With these notations, the dynamical system governing the metabolic network can be written concisely as

$$V \frac{d\mathbf{X}}{dt} = \mathbf{S} \begin{bmatrix} \varphi \\ \psi \end{bmatrix} + \mathbf{r}, \quad (5)$$

where $\mathbf{X} \in \mathbb{R}^M$ is the vector of concentrations of all biochemical species, and the vector $\mathbf{r} \in \mathbb{R}^M$ is a vector containing all transports from outside the system. In practice, $\mathbf{r}$ comprises transports of metabolites through the blood flow and possibly losses through diffusion.

Observe that in order to solve the system, we need to know how the fluxes φ and ψ depend on the metabolite concentrations, which requires a good understanding of the biochemistry and physiology. In the following subsections, we elaborate further on their explicit expressions.

Flux Balance Analysis Flux balance analysis (FBA) refers to the analysis of the steady states in a metabolic network (Schilling et al. 2000; Kauffman et al. 2003). Because in a steady state the metabolite concentrations are time invariant, the derivative on the left hand side of the model (5) vanishes, leading to the linear system

$$\mathbf{S} \begin{bmatrix} \varphi \\ \psi \end{bmatrix} = -\mathbf{r}. \quad (6)$$

where the unknowns are the fluxes, whose values must fall inside physiological ranges to be meaningful. For this reason, a straightforward solution of the linear system, e.g., in the least squares sense, is typically useless.

In order for the system to respect the conditions for the cells to be alive, several of the fluxes have to be nonnegative. This is the case for those associated with irreversible enzymatic reactions, such

as those that are part of glycolysis or oxidative phosphorylation. The same holds for some of the transports. Furthermore, the maximum reaction flux or transport rate is regulated by the expression of the enzyme or transporter facilitating the reaction, hence is typically bounded from above. Hence, in order for the computed solution to have an interpretation in terms of cell physiology, a number of bound constraints need to be implemented as part of the flux balance analysis.

The second observation is related to the non-uniqueness of the solution. If the matrix $\mathbf{S}$ has more columns than rows, as is often the case, it has a nontrivial null space, consisting of all non-zero vectors that satisfy

$$\mathbf{S} \begin{bmatrix} \varphi_0 \\ \psi_0 \end{bmatrix} = 0.$$

Any vector from the null space can be added to any solution of the Eq. (6) without affecting the equilibrium. The presence of the null space may be interpreted as the necessary leeway of the system to adjust itself, should the conditions of the environment change, making this concept particularly useful from the point of view of understanding the capabilities and limitations of the system. Characterizing the null space under bound constraints in the flux balance analysis is not a trivial task due to the high dimensionality of the flux space. A systematic description of the set of all possible solutions requires the use of sampling methods to generate a significant ensemble of possible solutions by using Monte Carlo or quasi-Monte Carlo techniques. This ensemble can be summarized in terms of its mean and credibility intervals (Papin et al. 2004; Wiback et al. 2004; Heino et al. 2010) or used to find histograms of single fluxes, or correlations between fluxes. This approach has been applied to brain

energy metabolism: see, e.g., Occhipinti et al. (2007, 2008, 2010), Calvetti and Somersalo (2012), Massucci et al. (2013), Calvetti et al. (2016), and DiNuzzo et al. (2016); for an extension incorporating genomic information, see Becker et al. (2007) and Lewis et al. (2010).

Dynamic Models All biochemical reactions in cells are enzymatic. Enzyme kinetics is a vast topic (Marangoni 2003; Cornish-Bowden 2012), as different enzymes have their characteristic reaction facilitating mechanisms and regulating factors, such as the ambient pH. Quantitatively, however, enzyme kinetics models have some common features, most prominently maximum reaction rates dependent on the expression level of the enzymes, and characteristic saturation rates. One of the simplest mathematical descriptions of enzyme kinetics comprising these two features is the Michaelis–Menten model, which can be derived from different assumptions concerning the enzyme action. Denoting by e the enzyme, the simplest enzymatic reaction type can be written as

where the intermediate phase Ae typically represents a fast transient. The Michaelis–Menten expression for the associated reaction flux is of the form

$$\varphi = V_{\max} \frac{[A]}{K + [A]},$$

where $V_{\max}$ is the maximum reaction rate and K is the affinity constant indicating the concentration level $[A]$ of A at which the reaction rate is one half of the maximum. Smaller affinity constant means faster saturation of the reaction. The characteristic time constant of the reaction is proportional to the ratio $K/V_{\max}$.

Reactions requiring the participation of the facilitator pairs ATP/ADP or NADH/NAD⁺ are regulated by the availability of these cofactors. Detailed modeling of the dependency requires that the details of each reaction are well understood. A useful approximation is obtained by

following the principle that, qualitatively, when there is abundance of the needed cofactor, the reaction rate follows the Michaelis–Menten kinetics, while scarcity of the cofactor lowers the maximum reaction rate. Consider reactions of the type

and define the phosphorylation state p and the redox state r of the compartment where the reaction occurs by

$$p = \frac{[\text{ATP}]}{[\text{ADP}]}, \quad r = \frac{[\text{NADH}]}{[\text{NAD}^]}.$$

Modifying the Michaelis–Menten kinetics model, we write the related reaction fluxes as

$$\varphi = V_{\max} \frac{p}{p + \mu} \frac{[A]}{K + [A]} \quad \text{or}$$

$$\varphi = V_{\max} \frac{r}{r + \nu} \frac{[A]}{K + [A]},$$

respectively, where $\mu > 0$ or $\nu > 0$ are the affinity constants of the phosphorylation or redox state. Conversely, reactions of the type

are quenched in the absence of ADP or NAD⁺, respectively; hence, the corresponding fluxes can be modeled, respectively, as

$$\varphi = V_{\max} \frac{1/p}{1/p + \mu} \frac{[A]}{K + [A]}, \quad \text{or}$$

$$\varphi = V_{\max} \frac{1/r}{1/r + \nu} \frac{[A]}{K + [A]}.$$

Some reactions may require both redox and phosphorylation cofactors. For instance, the flux

of the glycolytic reaction (1) in this modeling framework would take the form

$$\varphi = \frac{1/r}{1/r + v} \frac{1/p}{1/p + \mu} \frac{[\text{Glc}]}{K + [\text{Glc}]}.$$

The transport fluxes can be modeled in a similar manner. The transport of a substance A from compartment x to compartment y effectuated through a membrane-bound protein X may be viewed akin to an enzymatic reaction,

where A_x and A_y refer to the same metabolite in different compartment, and AX is the fast transient state corresponding to the membrane passage. A natural Michaelis–Menten type model for the flux of this transport is

$$\psi = T_{\max} \frac{[A_x]}{M + [A_x]},$$

where $T_{\max}$ is the maximum transport rate and M is the affinity. The above model assumes a unidirectional transport; in the case of bidirectionality, the net transport flux becomes

$$\psi = T_{\max} \frac{[A_x]}{M + [A_x]} - T'_{\max} \frac{[A_y]}{M' + [A_y]},$$

where the maximum transport rate $T'_{\max}$ and affinity M' of the reverse transport may or may not be equal to the ones of the forward transport.

Transport by passive diffusion through concentration gradient across the membrane is usually modeled by Fick's law,

$$\psi = \lambda([A_x] - [A_y]).$$

A major challenge of dynamic metabolic modeling using parametric models is the fact that the number of model parameters increases concomitantly with the complexity of the model, and finding reliable values for the parameters is not easy. Several factors contribute to the ambiguity about the values of the model parameters.

First, the expression levels of different enzymes and transporters are poorly known and vary widely; second, in vitro measurements may not translate reliably to the in vivo and in situ settings; third, the regulatory factors are numerous, variable, and poorly known. Other factors, like mitochondrial density, may also affect the model. At the moment there is not a complete agreement on how geometric factors such as the vicinity of astrocytic end feet to capillaries and the transport across the blood–brain barrier should be taken into account (Serlin et al. 2015).

Several dynamic metabolic models have been published in the past decades, but because of the reasons mentioned above, no one is considered the gold standard model. For details and specifics of each model, we refer to Gruetter et al. (2001), Aubert and Costalat (2002, 2005), Simpson et al. (2007), Cloutier et al. (2009), DiNuzzo et al. (2010), Calveti and Somersalo (2011), and Calveti et al. (2015).

Spatially Distributed Models In the literature, most of the metabolic models of the brain assume a well-mixed compartment structure. However, there are several reasons why a spatially distributed model could be of interest. One is that lumped models do not account for diffusion, in particular of oxygen, which may be a rate limiting factor for energy metabolism. Indeed, the classical investigations of A. Krogh suggested that the capillary density needs to be quite high in order for brain tissue to remain well oxygenated. A second argument is that assuming spatially invariant mitochondrial density could bias the balance between aerobic and anaerobic metabolism. A big challenge for designing a mathematical model that accounts for spatial inhomogeneity is the extremely complex and poorly known geometry of neurons and astrocytes. In Calveti et al. (2015), the geometric complexity was avoided by introducing an effective multidomain reaction-diffusion model, akin to the bidomain model widely used in modeling the myocardium.

An additional motivation for developing spatially distributed models is the fact that spatial distribution of the metabolic processes will play a significant role in understanding phenomena like the cortical spreading depression: The

depolarization wave is known to propagate through the brain tissue, and many important questions are related to the interplay of depolarization, metabolic activity, and hemodynamics. The challenges of building a realistic distributed model are significant.

Towards Coupled Metabolism and Electrophysiology The foundation of the mathematical description of neuronal signal propagation along the axon is the classical Hodgkin–Huxley model, governed by a system of coupled differential equations for the membrane voltage potential V and three gating functions regulating the sodium influx and potassium efflux (Keener and Sneyd 2009). An important assumption of the model, well justified in the famous experimental setup with the giant axon of the squid, is that the reversal potentials are constants. Using the Nernst equation, the reversal potentials are given in terms of the ion concentrations inside and outside the cell. For the squid giant axon, it is realistic to assume that these concentrations do not change, but in the microscopic environment of brain neurons, such assumption is no longer realistic: A small potassium flux out of the neuron can change significantly the potassium concentration in the very narrow extracellular space, and the astrocyte intervention is needed to restore it.

Models which couple ion concentrations to pump actions in neurons and astrocytes have recently appeared in the literature; in Cressman et al. (2009) and Barreto and Cressman (2011), the authors couple the extracellular and intracellular sodium and potassium concentrations through an algebraic equation, and account for the sodium–potassium pump effect as well as the glial potassium cleaning, and potassium diffusion out of the system. A step forward towards the coupling of the electrophysiology to metabolism was taken in Wei et al. (2014) where the authors add an oxygen-dependent regulator to the sodium–potassium flux of the neuron. This is tantamount to assuming that ATP production is based on aerobic metabolism and that the ATP level responds without a delay to oxygen availability: However, the details of metabolic processes are omitted, and the energetic need of the astrocyte is not included.

In the metabolic modeling literature, the idea of coupling of the metabolic needs of the neuron and the ion dynamics is not new: In Aubert et al. (2001), for example, the influx of sodium is used as an external trigger of the elevated metabolic rate; however, the feedback mechanism coupling the ion dynamics and metabolism has been included only recently. In Jolivet et al. (2015), the metabolic model of Aubert and Costalat (2002) is coupled with the basic Hodgkin–Huxley model. In Calvetti et al. (2018), the electrophysiological model of Cressman et al. (2009) was coupled with the neuron-astrocyte complex metabolic model in Calvetti and Somersalo (2011), including a phosphorylation state-dependent factor both in the neuronal sodium–potassium pump action and in the glial potassium flux. This implies that both neuron and astrocyte need a steady supply of metabolites to guarantee the ion balancing. While in neuron the energetic cost of the ATPase to sustain the sodium–potassium pump action is relatively well known, the energetic need of glia remains somewhat of a mystery. In particular, the potassium cleaning per se is not ATP-dependent, yet it is believed that in order to be functional, astrocytes use a significant percentage of the total energy budget of the brain (Hertz et al. 2007), justifying a phosphorylation level control in astrocyte also.

Integrating the Neurovascular Coupling

Much of our current understanding of the functioning brain is based on brain imaging methods, such as blood oxygenation level-dependent functional MRI (BOLD-fMRI), with the implicit assumption that elevated electrophysiological activity triggers an increase in the supply of oxygenated blood at the same location, so that an observed elevation in blood flow can be used as a proxy for elevated activity. While experiments confirm that the basic assumption is valid (Logothetis et al. 2001), the details of the neurovascular connection are not completely understood. It has been suggested that the vasodilation is due to a signal that could consist of increased extracellular potassium concentration (Filosa et al. 2006), astrocytic regulation through the end feet (Nortley and Attwell 2017), increased lactate concentration (Fox et al. 1988; Mintun et al. 2004), nitric oxides

from the neurotransmission related glutaminase (Lourenco et al. 2016), or a combination of all of them. Given that every one of the proposed mechanisms is directly related to the cell energy metabolism, instead of referring to neurovascular coupling, it would be more correct to use neuro-metabolic-vascular coupling to underline the crucial role of the energy metabolism.

Two classical models explaining qualitatively the origin of the BOLD signal are known as the balloon model (Buxton et al. 1998) and the Windkessel model (Mandeville et al. 1999; Kong et al. 2004). These models have been developed further since they were originally published, to better understand the coupling with neuronal activity: To this end it is important that the model is more specific in identifying the vascular compartment susceptible to activity-induced dilation. Unlike the arterial and venous vessels, the vascular walls of capillaries do not have smooth muscles; hence, it is natural to hypothesize that the main increase in blood volume following neuronal activation is accommodated by arteries and veins whose compliance increases, although capillary recruitment during activity is not ruled out. Current literature seems to be in favor of the hypothesis that the arterial compartment is mostly accommodating the increased blood flow.

The blood flow has been incorporated from early on in some metabolic models in the literature, mostly to give an interpretation to the BOLD

signal in terms of the metabolic activity, see, e.g., Aubert and Costalat (2002). However, models integrating the blood flow and metabolism including a two-way feedback mechanism are still missing, although there has been some recent work towards integrating the oxygen dynamics in tissue with multicompartment vascular models (Zheng et al. 2005; Kocsis et al. 2006; Huppert et al. 2007).

In Barrett et al. (2012), the authors developed a three-compartment model for coupling the neurovascular stimulus and blood flow, without elaborating on what comprises the signal. The model exploits the analogy of the blood system with an electric circuit as shown in Fig. 5, whose governing equations can be deduced from the circuit theory,

$$p_j = \rho_j f_j + \frac{V_j}{C_j}, \quad \frac{dV_j}{dt} = f_j - f_{j+1}, \quad 1 \leq j \leq 3,$$

where $j = 1$ corresponds to arteries, $j = 2$ to capillaries, and $j = 3$ to veins, p_j is the entry blood pressure, V_j is the compartment volume, ρ_j is the resistance, C_j the compliance, and, finally, f_j the blood flow. The authors assume that the blood moves through the vascular system according to a Poiseuille flow, leading to a resistance model

Brain Energy Metabolism, Fig. 5 The analog electric circuit corresponding to the three compartment cerebral blood flow model. Each compartment is divided symmetrically in half, each half contributing equally to the resistance of the blood flow. The pressures p_j correspond to

voltages, the blood flows f_j correspond to electric currents, resistivities ρ_j correspond to electric resistances, volumes V_j of the compartments are treated as charges, and finally, compliances C_j of the compartments correspond to capacitances

$$\rho_j \propto \frac{1}{V_j^2},$$

while the viscoelastic properties of the vessels regulating their compliance are modeled as

$$C_j = C_j^* \left(\frac{\kappa_j - V_j/V_j^*}{\kappa_j - 1} - v_j \frac{dV_j}{dt} + s_j(t) \right),$$

$$1 \leq j \leq 3,$$

where C_j^* and V_j^* are the baseline compliances and volumes, κ_j is the stiffness, v_j is the viscoelastic constant and, most importantly, $s_j = s_j(t)$ is the vasodilatory stimulus associated to the compartment. The presence in the formula of the derivatives of the volumes makes this a nonstandard system which, in the cited articles, is treated as a differential-algebraic system. The explicit dependence of the model on the unspecified stimulus function provides a good starting point for coupling it with metabolic and electrophysiological models by establishing a connection through the stimulus function originating from the metabolic model, while coupling backwards the resulting blood flow to the metabolite supply. Such integrative process has been recently initiated in Capo Rangel et al. (2018), where the stimulus function is interpreted to be proportional to the potassium concentration in the extracellular space.

Extracellular compartment; Interstitial space; Interstitial volume

Definition

The extracellular space (ECS) comprises a system of contiguous narrow spaces interposed between the brain cells. It occupies approximately 20% of the brain tissue volume. Mathematical modeling quantifies the macroscopic parameters of the ECS from experimental data obtained with diffusion analysis and tests the hypotheses about the ECS microstructure.

Detailed Description

The ECS is filled with ionic solution and macromolecules of the extracellular matrix. Its structure is determined by the shape of brain cells (neurons and glia) and their processes (axons and dendrites), the width of pores

between the cells, and the extracellular matrix (Fig. 1). The ECS is fundamentally important for the brain function as it complements neuronal and glial networks. Instead of merely filling the void between the brain cells, as its name might suggest, the ECS exerts a direct influence on many essential processes in the brain, including the diffusion of neurotransmitters and neuromodulators mediating intercellular communication, the distribution of ionic currents, the cellular homeostasis, the neurotrophic effects, the transport of nutrients, and the clearance of metabolites. From the perspective of patient care, ECS forms the final segment of a delivery route for therapeutics destined for the brain cells. Therapeutic agents enter the ECS across the blood-brain barrier at a capillary, from the cerebrospinal fluid, or they are released directly into the ECS. The efficacy of treatment depends on the compatibility between the drug or its carrier and the ECS microenvironment.

It has been recognized that the ECS structure undergoes dynamic reversible changes during brain activity as well as transitions between sleep and awake brain states (Nicholson and Hrabetova 2017). It is also changed profoundly, and often irreversibly, by many pathophysiological processes associated with neurological disorders and brain tumors (Sykova and Nicholson 2008). The results of ECS research are thus important for understanding the brain function and challenges to the chemical traffic and drug delivery when the ECS structure is altered by pathophysiological processes.

In this entry, we will focus on the role of ECS as a route for molecular transport. Once introduced into the ECS, substances are transported predominantly by diffusion because the ECS lacks any active transport mechanism. Physiological effects of substances diffusing in the ECS are governed by their concentrations and their arrival times, which in turn depend on the ECS structure affecting the diffusion. Biophysical parameters of the ECS have to be taken into account whenever quantitative understanding of any diffusion-mediated process is desired.

pore width (double arrow), and extracellular matrix (green) are key components of the ECS structure. (Modified from Hrabetova S, *diffusion-fundamentals.org* 16 (2011) 3, pp. 1–2)

Experimental Approaches

Research of the ECS is challenging, in part because the ECS structure cannot be easily visualized, the interstitial pores being below the resolution of light microscopy. Electron microscopy studies provide indispensable information on topology, but they require tissue processing methods known to diminish the ECS volume, and they also cannot quantify parameters of the extracellular matrix or visualize dynamic changes of the ECS structure (Sykova and Nicholson 2008). In contrast, emerging super-resolution imaging techniques that break the diffraction limit are beginning to provide much needed information on the ECS microstructure and nanoscale diffusion in the living brain tissue (Hrabetova et al. 2018).

Currently, the common experimental approach uses diffusion measurements to indirectly obtain information on the ECS structure (Nicholson 2001; Nicholson and Hrabetova 2017). In a diffusion experiment, molecules are released from a point source, and their subsequent ECS concentration is detected either by special ion-selective microelectrodes (Real-Time Ionophoretic method) or by optical imaging (Integrative Optical Imaging) and analyzed as a function of position and time. In diffusion experiments employing

small extracellular probe molecules, two macroscopic parameters of the ECS structure are quantified: the volume fraction and the hindrance. Volume fraction α is a proportion of the tissue volume occupied by the ECS ($\alpha = V_{\text{ECS}}/V_{\text{tissue}}$). Hindrance describes how much the diffusion process in an ECS environment slows down in comparison with an obstacle-free medium. It can be expressed as the diffusion permeability $\theta = D^*/D_{\text{free}}$, where D^* is an effective (i.e., averaged over a small neighborhood volume) diffusion coefficient in the brain tissue and D_{free} is a free diffusion coefficient (Hrabe et al. 2004) or as the tortuosity $\lambda = \theta^{-1/2}$ (Nicholson 2001). In an isotropic brain tissue, α is about 0.20, and θ is about 0.4 ($\lambda = 1.6$) (Sykova and Nicholson 2008). The ECS is a dynamic structure, and its volume fraction and hindrance change, often independently, during brain activity and in disease (Sykova and Nicholson 2008). For example, during a stroke, α is as low as 0.07 and θ decreases to 0.23 ($\lambda = 2.1$), while in malignant brain tumors α expands to 0.48 and θ decreases to 0.32 ($\lambda = 1.8$). The ECS volume and hindrance are two essential ECS parameters which determine concentration and arrival times of substances diffusing in the ECS.

Diffusion measurements that employ larger extracellular probe macromolecules are able to

separate the influence of complex ECS geometry from the constrictivity factor, which describes an additional hindrance due to frequent proximity of macromolecules to the cellular walls (Nicholson and Hrabetova 2017). According to the restricted diffusion theory, the constrictivity depends on the average width of the ECS pores, which can thus be estimated. This approach leads to an estimate in the range of 38–64 nm. Another approach combined diffusion measurements with the scaling theory developed in polymer physics to obtain an estimate of 31 nm. The individual ECS pores of a living brain tissue are therefore much wider than the 15–20 nm typically obtained with electron microscopy. The width of extracellular pores is an essential parameter for drug delivery strategies because it provides an upper limit for the size of particles (e.g., liposomal and viral drug carriers) that can uniformly penetrate the ECS and access cells in an unrestricted manner.

Computational Approaches

Computational approaches are indispensable in the ECS research. At a macroscopic level, an appropriate solution of the diffusion equation is fitted to the data obtained in a diffusion experiment to extract the ECS parameters. The most general form of the diffusion equation accounts for an anisotropic environment and allows both the volume fraction and the diffusion permeability (a tensor quantity in this case) to become inhomogeneous (Arranz et al. 2014):

$$\begin{aligned} \frac{\partial c(\vec{r}, t)}{\partial t} = & \frac{D_{\text{free}}}{\alpha(\vec{r})} \\ & \nabla \cdot \left[\alpha(\vec{r}) \boldsymbol{\theta}(\vec{r}) \cdot \nabla c(\vec{r}, t) \right] \\ & + \frac{s(\vec{r}, t)}{\alpha(\vec{r})} - \kappa(\vec{r}) c(\vec{r}, t), \end{aligned}$$

where $c(\vec{r}, t)$ is the concentration at position $\vec{r} = (x, y, z)$ and time t , D_{free} is the diffusion coefficient in obstacle-free medium, α is the ECS

volume fraction, $\boldsymbol{\theta}$ is the diffusion permeability tensor, s is the source strength, and κ is the non-specific linear clearance approximating a loss proportional to the concentration. This equation has to be solved numerically in this general form. However, several analytical solutions exist under simplifying assumptions often used in practical measurements.

The ECS parameters extracted from diffusion measurements are the result of macroscopic averaging of a geometrically complex microscopic environment and consequently do not provide information about the ECS features at a microscopic level. Very little is known about the local structure of individual ECS pores, their organization, and statistical distribution of their parameters. Monte Carlo simulations of molecular diffusion in simplified three-dimensional ECS models are used to test various hypotheses about the microscopic ECS features. One important simulation tool is the *MCell* (Monte Carlo Cell) package (Stiles and Bartol 2001; www.mcell.psc.edu). It was designed for biologically oriented users and uses a simple model description language to specify simulation components such as the cellular surfaces and reaction mechanisms.

Monte Carlo simulations have been used to simulate diffusion of molecules in media constructed of simplified cell shapes that allow tight packing (Tao and Nicholson 2004; Hrabec et al. 2004). They revealed that an extracellular environment with convex cellular elements cannot have diffusion permeability θ lower than $2/3$, which is far above the typical experimental value. This led to the development of a model of hindrance based on diffusion dwell times (Hrabec et al. 2004). More complex shapes were introduced, which included concave cellular geometries. The volume fraction α was divided into the well-connected (α_o) and dead-space (α_{ds}) parts. A new relationship between the θ and α was obtained, namely,

$$\frac{\theta}{\theta_0} = \frac{\alpha_o}{\alpha_o + \alpha_{ds}} = \frac{\alpha_o}{\alpha}.$$

This model of the ECS composed of both convex and concave cells can explain diffusional

hindrance measured in the brain under normal as well as some pathological conditions. It predicts that about 40% of the brain ECS under normal conditions is formed by dead spaces increasing to 60% in a stroke (Hrabetova and Nicholson 2004). In practice, the local ECS geometry probably varies continuously between the well-connected spaces and dead spaces, including features such as lake-like openings.

Another factor which manifests itself by increased hindrance is the fast reversible binding of molecules to the binding sites in the extracellular microenvironment. Comparing diffusion measurement with molecules of similar sizes but distinguished by their chemical interactions, it is possible to extract the respective reaction rates (Nicholson and Hrabetova 2017).

Conclusions

Brain ECS facilitates intercellular communication, nutrient and metabolite trafficking, and the delivery of drugs. ECS research combines diffusion experiments in the brain with computational modeling approaches to characterize the microstructure of the ECS and discover how it is regulated. The results are important for understanding the workings of the brain under physiological conditions and in various neuropathological states, which often affect the ECS properties and result in disrupted traffic of ions, signaling molecules, and nutrients. They are also essential for the design of effective drug delivery strategies in patients suffering from neurological disorders and brain tumors. The ultimate goal of the ECS research is to construct a dynamic three-dimensional model of the brain ECS.

Definition

Cerebral ischemia, which occurs during stroke, is insufficient blood flow to the brain and leads to loss of oxygen and glucose supply. This severely compromises cellular respiration, causing neuronal damage. Cells move toward cell death, which can be simplified as being controlled, e.g., apoptosis, and uncontrolled, e.g., necroptosis, and as intrinsic (due to changes in the cell) or extrinsic (resulting from extracellular signals). There are more than 12 kinds of cell death, and inhibition of multiple death pathways may be necessary for neuroprotection (Fricker et al. 2018). Ischemic stroke is a multiscale phenomenon, involving a cascade of events at spatial scales from organelles (e.g., loss of mitochondrial membrane potential) to tissue and temporal scales from milliseconds generation of action potentials to years for the restructuring of networks. Ischemic insult also involves transcriptional changes to regulatory networks of genes. Taken together, modeling the molecular and genetic aspects of ischemia is fundamental to understanding how to modulate neuroprotective elements in the case of stroke, which is the primary therapeutic approach in saving at-risk tissue. Computer-based cellular modeling can assist in understanding the molecular changes involved, the decision and control points for various cell fates, and the potential for recovery with partial damage and help define the scope of the genetic and regulatory network changes that occur.

Detailed Description

The mechanisms by which cells accumulate damage, signal damage to neighboring cells, and eventually die all remain unclear. The geometric complexity of neurons makes it difficult to elucidate single-cell diffusive mechanisms in the ischemic signaling cascade. Further complexity occurs due to difficulties in disconnecting effects at the cellular level from effects at the tissue level, as well as effects due the synaptic interconnectivity of the neurons, which can lead to network

cascades in dying tissue. Compounding these difficulties is the fact that many signaling cascades are heavily interdependent on non-apoptotic, homeostatic mechanisms and have multiple non-linear dependencies. The intricacies of signaling pathways that are potentially involved in cell death, both intracellular and intercellular, make it useful to study neuronal ischemia using multi-scale modeling, which can describe the effects across subcellular and cellular levels.

Blood enters the brain via a complex arterial tree. When arteries or large arterioles are damaged through occlusion or rupture, blood supply is locally reduced, causing ischemic damage. The degree of damage is highly variable, depending on the extent and duration of the insult. Generally, we conceptualize two major separable regions: an *ischemic core* where blood flow is essentially zero and an *ischemic penumbra* where there is some residual blood flow. The ischemic penumbra is a region that is considered a target for rescue by appropriate treatment. At normal body temperature, full ischemia for 3–5 min is generally lethal to neurons. However, irreversible damage in the penumbra can occur over several hours following ischemia. The cellular and molecular changes in these regions have markedly different presentations (Lipton 1999). Damage in the penumbra will be highly variable across multiple time-scales. The duration of oxygen deprivation that triggers the ischemic cascade and the extent of damage will likely depend upon genetic and environmental factors in the individual and in the precise types of cells involved. In particular, it is hypothesized that larger cells such as Purkinje cells and cortical pyramidal cells may be particularly vulnerable.

Nutrient Delivery

Ultimately, all ischemia results from loss of substrates for the cell to generate adenosine triphosphate (ATP), its primary energy currency. Computer models of nutrient delivery at the level of blood and of extracellular tissue are therefore useful in providing the setting for effects on the individual cell. This nutrient modeling allows

us to better define molecular differences in types of ischemia that will be produced. Simplified ischemia models at this level represent brain tissue as a set of voxels which exchange O_2 , with influx and outflux of blood between the regions and oxygen consumption integrated at each simulation time-step (Hudetz et al. 1982). In a paper published in 2002, Duval et al. (2002) modeled four parameters: cerebral blood flow, rate of oxygen extraction from blood, metabolic rate of oxygen use by tissue, and the apparent diffusion coefficient of water. A survival delay variable was also used to quantify the decay of tissue in the penumbra from functional to salvageable to necrotic. This modeling suggested that the penumbra could take on two major forms: ischemic and edematous. Ischemic penumbra tissue was metabolically altered and generally not salvageable, whereas the edematous penumbra tissue appeared to retain greater recovery potential. This model represented a first step toward clarifying how extracellular nutrient parameters might affect the generation of penumbral regions. Other models have included blood flow parameters in molecular models as a way of developing more robust models of cellular networks (Dronne et al. 2006).

Several findings relevant for ischemic stroke have come from modeling ATP production and consumption in a motor neuron, used to study amyotrophic lateral sclerosis (Le Masson et al. 2014). The model demonstrates the link between ATP required for an action potential and the neuronal geometry. Low ATP production in the model leads to a deadly positive feedback loop as the neuron consumes more ATP, because Na^+-K^+ pump activity is reduced so the neuron gradually depolarizes and the firing rate increases. It shows that Ca^{2+} accumulation is a by-product of energy failure, relevant for many of the death pathways involved in ischemia. By modeling the morphology of the motor neuron including both the dendrites and axon, the model was able to show how an energy crisis in a localized microdomain, such as the end of the axon can generate ectopic action potentials and hyperexcitability.

Initiation of the Ischemic Cascade

After vascular damage, neuronal uptake of O_2 and glucose is reduced, leading to a sequence of metabolic and molecular changes that span spatial scales from subcellular to tissue (Fig. 1). An early result of nutrient loss is a reduction in ATP. The biochemistry of energy production in brain tissue utilizes the same reactions that are used in other cells of the body. However, neurons are run at high metabolic states in order to maintain the electrochemical gradient that enables neurons to fire action potentials. They have additional ATP delivery challenges associated with the presence of long, thin processes with large surface to volume ratios. With disruption in ATP production, plasma membrane ionic gradients will begin to decay, preventing neuronal electrical function and allowing excitotoxic damage via calcium entry due to depolarized membrane potential. Loss of ion homeostasis may precipitate the accumulation of reactive oxygen species and intracellular calcium dysregulation, both of which are primary perpetrators of cell death (Lipton 1999). Models of this process are similar to the early work done by Magnus and Keizer in pancreatic β -cells, another electrically excitable cell type (Keizer and Magnus 1989). This model demonstrated that increased glucose concentration could enhance burst spiking, generating an elevated intracellular Ca^{2+} and excitotoxicity. Later work by Magnus and Keizer focused on developing more robust models of mitochondrial Ca^{2+} signaling (Magnus and Keizer 1998).

Similarly, in neuronal cells, loss of ATP due to poor blood flow triggers a cascade of reactions leading to apoptosis or necrosis. Four major mechanisms are recognized (Lipton 1999):

1. Influx of Ca^{2+} ions through NMDA receptors and voltage-gated Ca^{2+} channels
2. Increased intracellular Na^+ causes glutamate efflux, which also eventually leads to increased intracellular Ca^{2+}
3. Decreased ATP/ADP ratio producing a fall in intracellular pH
4. Production of free radicals, particularly near mitochondrial membranes

Brain Ischemia and Stroke, Fig. 1 The cascade of some of the key events following ischemic stroke. (Adapted from *Drug Discovery Today: Disease Models*, Vol.

19, Adam J. H. Newton and William W. Lytton, *Computer Modeling of Ischemic Stroke*, pp. 77–83, 2016, with permission from Elsevier)

Ionic dysfunction is a hallmark of both necrotic and apoptotic cellular changes. This dysfunction is primarily manifest via abnormal Ca^{2+} fluctuations within the cell. The generation of free radicals and inability to manage pH may also be tied to Ca^{2+} dysregulation via Ca^{2+} -binding control proteins such as calmodulin, calbindin, and calpain (Saftenku and Friel 2012). The products from these early reactions are heavily involved in the cell's final fate.

Due to the importance of Ca^{2+} and Ca^{2+} buffering in determining cell fate, much attention in

ischemia research has focused on modeling this ion. Normally, there are very low resting levels of Ca^{2+} in the neuron. This would ideally use stochastic modeling, because small concentrations of ions cannot be identified as bulk units, which can be handled deterministically. Such a deterministic approach (e.g., rate laws) relies on the law of large numbers; for many aspects of Ca^{2+} signaling, the concentration is so low that this law does not apply. It has been suggested, in fact, that the cell uses chemistry as a computational tool and is able to harness stochastic Ca^{2+} fluctuations to generate

robust intracellular signaling networks. Ischemic cascades therefore involve stochastic events as well as deterministic events, and both involve considerable species diffusion through neurons and extracellular tissue space. Modeling allows us to explore Ca^{2+} fluctuations and species diffusion at a very small-scale level.

Disruption of Homoeostasis

Typically mathematical and computational modeling of neurons assume ion homeostasis. Ion pumps powered by ATP or exchangers driven by concentration gradients are able to limit any changes resulting from the neuron firing. Such assumptions may be valid for physiological neuronal behavior. However, during pathological conditions like ischemia or seizure, the demands placed on the cell exceed its capacity to meet them. This is seen dramatically during spreading depolarization. Spreading depolarization is a wave of breakdown in the ion gradients in neurons and astrocytes resulting in almost complete depolarization. Spreading depression (SD) is the corresponding silencing of electrical additivity that results from this depolarization. SD causes secondary lesion growth in focal ischemia, (reviewed Hartings et al. 2017), which has also been shown with a phenomenological model of cell death based on energy supply and calcium concentrations (Chapuisat et al. 2008). SD can be triggered by many insults such as seizure, migraines, and traumatic brain injury and may not cause cell damage in normally perfused tissue.

Several mathematical models have explored ion (Wei et al. 2014) and glutamate (Hubel et al. 2017; Conte et al. 2018) homoeostasis using three compartments: intracellular, extracellular, and astrocytic. These models include several mechanisms to restore ion concentrations, including the Na^+/K^+ pump and glutamate transporters. Some also allow the cell volume to respond to changes in ion concentrations, primarily related to Cl^- homoeostasis. Cl^- homoeostasis is maintained by passive leaks (Kay 2017) or a balance between the chloride potassium symporter (KCC2) which tends to transport Cl^- into the cell and Na^+/K^+ –

Cl^- cotransporter (NKCC1) which tends to remove it. The extracellular concentration is treated as a bath, with diffusion slowly restoring the concentrations. These models have been used to show the range of behaviors that can be produced by the cell by modifying ion concentrations, from regular spiking activity to spreading depression and anoxic depolarization. They have explored the role of astrocytes in buffering K^+ and glutamate, the interplay between the Na^+/K^+ pump and the glutamate transporter reversal, and their role in generating recurrent waves of SD.

Ion concentrations have also been modeled in multicompartment neurons with dendrites (Kager et al. 2002; Somjen et al. 2008). These models have shown SD is ignited in the apical dendrites in an all-or-none fashion if the membrane current turns inward, leading to a positive feedback loop where more K^+ was released from the dendrite leading to even greater depolarization. Both the onset and duration of SD are modulated by glia buffering of K^+ . A limitation of these biophysically detailed models is that they consider the neuron in isolation with their own ECS and astrocyte. By considering a 1D (Conte et al. 2018) or 2D continuum (Tuckwell 2008), it is possible to model the propagation of waves of SD, e.g., speed and duration, and the form of the waves such as spiral, reverberating, or recurrent waves. However, these continuum models lack the finer-scale details of the underlying neurons. Tools have recently been developed for multiscale modeling to incorporate biophysically detailed neurons in a 3D macroscopic model of ECS (Solbra et al. 2018; Newton et al. 2018).

Use of Boolean Networks in Ischemia Modeling

The changes in nutrients, in ATP, in Ca^{2+} , etc. detailed above are only the beginning of a large array of interconnecting molecular changes. One way to make sense of such a complex and large network has been to use a Boolean Network (BN) formalism to model system dynamics. By conceptualizing the molecules in the signaling

networks as having a discrete set of states (ON/OFF or activated/repressed), interaction rules can be defined for a particular set of reactions. Mai et al. used BNs to model aspects of apoptosis (Mai and Liu 2009). They found downstream redundancies, feedback loops, points of control, and steps leading toward irreversible commitment to this endpoint. Although this approach simplifies reaction dynamics to a 0/1 decision tree, it can provide valuable information on system properties and points of modulation within the apoptotic pathway.

Therefore, the type of information that can be gleaned from a model depends very much on how the model is designed. One alternative to BN modeling is to use ordinary differential equation (ODE) kinetics to model Ca^{2+} wave propagation and reactivity with a higher degree of precision. Within this context, one can also model Ca^{2+} wave propagation and define parameters for wave oscillation interactions with other elements in the single cell. Such an approach, however, does not link Ca^{2+} waves to network pathological processes within and without the cell. Recently, Kazemzadeh et al. used a combined Boolean and ODE approach to model network regulatory effects of apoptosis in a modified (cf. humanized) yeast model. Using databases to generate robust Boolean networks that could then be solved at time-steps enabled them to calculate steady states of complex apoptotic networks and to test the effects of genetic knockouts and variable ischemic insults (Kazemzadeh et al. 2012). Another set of experiments by McDermott et al. was aimed at using BN formalism to study regulatory gene networks in response to ischemic insult. They modeled clusters of functionally related gene elements in steady state and then perturbed this system by using various types of preconditioning insults, including mild ischemia, and a later more serious ischemic insult. Results between the various initial states were compared, and the functional significance of genetic contribution to neuroprotection was analyzed by looking at the robustness of cluster response to preconditioning (McDermott et al. 2012). Most of the results from the computer model were confirmed by previously published experimental data. BN formalism

is a reductionist view of network signaling, whereas simultaneous ODE solving at discrete time-steps gives a larger picture of intracellular signaling. Attempts to link these two modeling methods in studying apoptosis and ischemic cascades have been gaining popularity in computational neuroscience as well as systems biology (Bogda et al. 2013).

Future Considerations

Computer modeling affords several advantages in the study of ischemia. It allows us to accurately measure many reactants simultaneously in exceedingly complex environments. We can link top-down and bottom-up models of ischemia to create robust multicellular models. We have also begun to understand how genetic regulation and preconditioning effects may confer neuroprotection. And, importantly, we can identify control points for cascade modulation, which are appropriate targets for therapeutic intervention. Such research will likely provide proof of concept and system extrapolation for the development of new drugs to encourage recovery or enhance the duration of recoverability in the penumbra.

BrainInfo

Douglas M. Bowden
Department of Psychiatry and Behavioral Sciences, School of Medicine, University of Washington, Seattle, WA, USA

Definition

BrainInfo can be thought of as a Web-based handbook of neuroanatomy. It is an authoritative resource for computational neuroscientists and others who need a quick in-depth orientation to specific structures in the central nervous system (CNS). BrainInfo has three components. The **BrainInfo Portal** provides extensive descriptive information and images of some 2500 brain structures; **NeuroNames** is a neuroanatomical ontology that provides standard English names for the structures plus 13,000 synonyms in eight languages; and **NeuroMaps** provides brain atlases of the macaque and mouse together with tools for mapping data and processing images for publication.

Detailed Description

The BrainInfo Portal (<http://braininfo.org>)

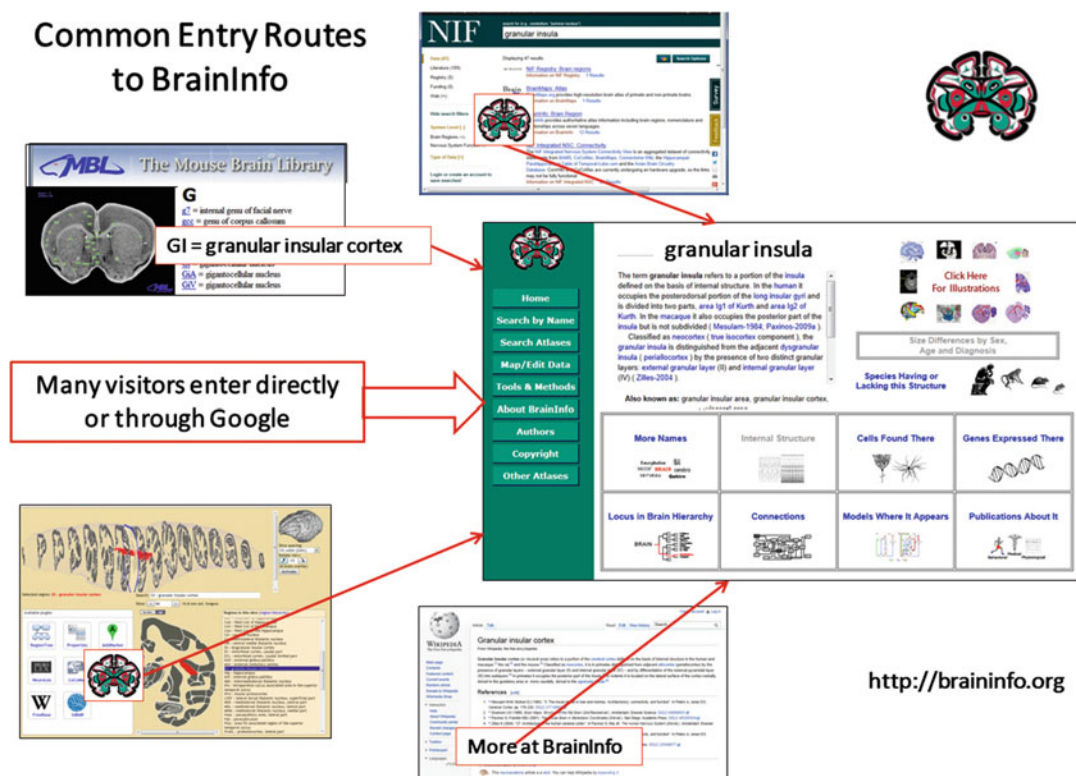

Users enter the Portal by several routes. Most enter via Google or via a page that they have previously bookmarked. Many also enter through

other websites that focus on a specific aspect of neuroanatomy, such as the brain of a particular species or the inputs and outputs, cell types, or gene expression in structures. Such sites link to BrainInfo to give users one-click access to a wider range of information on specific neural structures (Fig. 1). A guide to use of the Portal is found at Bowden and Dubach (2005).

BrainInfo, in turn, links out to pages in some 50 other websites to provide users access to information and illustrations of some 2500 structures and superstructures in the CNS of the four species most studied by neuroscientists: the human, macaque, rat, and mouse (Fig. 2, SPECIES). With more than a thousand distinct cell groups identified in the mammalian brain, mastering the neuroanatomy is a challenge. The challenge is magnified several times by variability across species, methods of identification, and nomenclature (Bowden and Martin 1997).

The Portal is designed particularly for neuroscientists who work in disciplines other than anatomy. It is for those whose knowledge of neuroanatomy is limited and who need rapid access to information that is scattered under a variety of names and across numerous publications and websites. The computational neuroscientist who comes upon an unfamiliar structure in a model system, or the psychiatrist who encounters an unfamiliar structure in reading about the neural mechanism of a classical disorder, can *Search by Name*, and BrainInfo will display the Central Directory to a wealth of text and images of the structure (Fig. 2).

The geneticist or molecular biologist who finds gene expression in an unfamiliar brain area can *Search Atlases*, find the area, and click it, and BrainInfo will display the Central Directory for the structure together with its standard name, a

BrainInfo, Fig. 1 Visitors enter BrainInfo either directly, through Google, or through links from many other websites including the Neuroscience Information Network

(NIF), the Mouse Brain Library (MBL), the Scalable Brain Atlas, and Wikipedia

BrainInfo Links Out to Pages in Other Sites

BrainInfo, Fig. 2 The BrainInfo Portal links out to pages deep in some 50 other neuroscience websites that illustrate most accurately, clearly, and thoroughly the anatomical

relations and internal features of CNS structures in the human, macaque, rat, and mouse

brief description, illustrations, kinds of neurons it contains, inputs, outputs, and so forth.

NeuroNames (<http://braininfo.rprc.washington.edu/Nnont.aspx>)

Neuroanatomical terminology is unusually confusing. Beginning in the late 1800s, scientists in multiple countries, studying the brains of many species, and publishing in multiple languages, contributed an overwhelming array of redundant and overlapping terms to the vocabulary (Bowden and Martin 1997). The typical brain structure has an average of six English and Latin names, many of which appear in the text and labels of today's publications and websites. The *standard nomenclature* of NeuroNames reflects an attempt to relate every name of a CNS structure in the neuroscience literature to a defined structure and to select one of those terms as its standard name.

All anatomical information in BrainInfo is indexed according to the standard nomenclature of the NeuroNames ontology. The ontology defines the relations between ~15,500 *names* (character strings), for ~2500 *concepts* (definitions) of the *entities* (structures) they represent in different *models* (hierarchies or networks) of CNS organization (Fig. 3).

The NeuroNames ontology allows visitors at the input interface of BrainInfo to *Search by Name* using not only the standard term but any synonym or homonym for the structure of interest. It includes all English terms for all structures and names for the most common ~1000 structures in seven other languages: French, German, Indonesian, Italian, Latin, Russian, and Spanish. On the output side, when BrainInfo sends a visitor to a website that uses a different name than the NeuroNames standard, a message box in the

BrainInfo, Fig. 3 NeuroNames is an informatics tool for resolving neuroanatomical ambiguities (Bowden et al. 2012b). In neuroanatomy, the same name (*left panel*) can represent multiple concepts (the homonym problem); and the same structural concept, or model composed of structural concepts (*central panel*), can have multiple names (the synonyms problem). A given model includes multiple concepts, and the same concept can occur in multiple models. Different scientists can hold different concepts of the same entity (*right panel*) and can model a complex entity in different ways. The NeuroNames ontology resolves naming and conceptual ambiguities by assigning a unique standard name to each concept and specifying the relations of all other names (as synonyms or homonyms) to the standard name and its concept

sidebar informs the visitor, “Look for [*the local name*].”

Developers of other neuroscience websites use NeuroNames to index databases in the standard nomenclature and to allow visitors to enter their websites using any synonym for structures (Bowden et al. 2012a). The ontology is freely downloadable from BrainInfo in either XML or Excel format. Both versions include the web address (URL) of BrainInfo’s Central Directory for each structure, which allows developers to link their visitors to BrainInfo for more information (Fig. 1).

NeuroMaps (<http://braininfo.rprc.washington.edu/MapViewData.aspx>)

Neuroanatomy is the common ground of the various neuroscientific disciplines. All data, whether of gene expression, functional MRI activity, or neuronal firing patterns, are related through the site in the brain from which they are recorded. NeuroMaps provides standard atlases of the

BrainInfo, Fig. 4 The NeuroMaps image processor enables users to adjust the size, colors, labels, and resolution of images for projection and publication. Here, the boundaries of cytoarchitectural areas in the cerebral cortex

of the mouse in the Allen Brain Atlas (AIBS 2008) have been mapped to the NeuroMaps symmetrical version of the Waxholm mouse brain (Bowden et al. 2011)

BrainInfo, Fig. 5 NeuroMaps illustrations: (a) dopaminergic cells at the gray-white boundary of prefrontal cortex (Dubach 1994) and (b) a lesion of lateral prefrontal cortex

that produces a top-down attentional deficit in macaques (Rossi et al. 2007)

macaque and mouse brains to which investigators can map data of all modalities for comparison, projection, and publication.

Each NeuroMaps atlas is based on a high-resolution MRI (magnetic resonance image) oriented according to standard stereotaxic practice for the species; the left and right hemispheres are identical to ease comparison of data mapped to the two hemispheres (Bowden et al. 2011). NeuroMaps tools allow the investigator to slice, tilt, and rotate the atlas MRI to match the plane of section of tissue bearing the data. They allow the designation of unlimited pairs of registration points to match landmarks in the experimental image to landmarks in the atlas. The investigator draws boundaries around data areas in the experimental image. A mapping tool automatically transfers them by a nonlinear process to corresponding locations in the atlas. Image processing tools enable the investigator to size, color, label, and adjust the resolution (dpi = dots per inch) of the merged image to match specifications of the journal where it is to be published (Fig. 4).

The NeuroMaps image processor can display data in multiple formats. The cross-sectional display of areal data (Fig. 4; BrainInfo 2013a) is suitable for mapping fMRI activation, gene expression, lesions, injection sites, and projection areas. Similar cross-sectional displays are used for mapping point data: stimulation sites, recording sites, and individual neurons stained for specific enzymes, receptors, or neurochemistry (Fig. 5a).

The three-dimensional MRI model is suitable for mapping surface areas, such as architectonic areas and cortical lesions (Fig. 5b; BrainInfo 2013b).

Brain-Machine Interface and Neuroimaging

Mitsuo Kawato

Computational Neuroscience Laboratories, ATR Brain Information Communication Research Laboratory Group, Kyoto, Japan

Synonyms

[Brain computer interfaces](#); [Neural prosthetics](#)

Definition

Brain machine interfaces (BMIs) directly connect brain activity and devices outside the brain for such purposes as sensory substitution, motor compensation and enhancement, neurorehabilitation, suppression of maladaptive neural circuits, and treatment for brain lesions and neurological and psychiatric disorders. A BMI usually consists of some of the following electrical, mechanical, and computing elements: a brain activity measurement system (electrodes, amplifier, AD converter, etc.), a computer for decoding brain information and/or controlling stimuli to the brain, an effector system (prosthetic limb, rehabilitation robot,

computer cursor, etc.), and a neural stimulation system.

Detailed Description

BMIs can be classified from at least the following three viewpoints. The first classification concerns which brain function is substituted, compensated, enhanced, or cured by BMI. Only three very basic functions are listed here: sensory processing, central decision-making, and motor control, which includes communication. The second addresses the BMI's objective: the substitution, compensation, and enhancement of lost or normal brain functions, or the cure, recovery, and rehabilitation of degraded brain functions. The third classification of BMI is whether it is invasive, i.e., whether it uses thin wire electrodes, semiconductor electrodes, electrocorticograms (ECoG; EEGs directly attached to the cerebral cortex surface), deep brain electrodes for brain activity measurement and/or electrical stimulation; or whether it is noninvasive, using scalp EEGs, fMRIs, NIRSSs, and so on. Theoretically, we have $3 \times 2 \times 2 = 12$ different BMI classes, but only a few have become practical. Below we explain some of the roughly two thirds that are actively being developed.

1. An artificial sensory organ or sensory BMI is an invasive system of sensory-function substitution for handicapped people. Artificial sensors, such as microphones or CCD cameras, measure auditory or visual signals and are transformed as inputs to a neural stimulation system with multiple electrodes that electrically stimulate the peripheral sensory nerves or the central nervous system. The oldest, most successful example, with 30 years of practical usage, is the cochlear implant. Artificial retinas have also nearly become practical. Visual cortex stimulation (artificial vision) and artificial vestibular systems are under active research and development.
2. A Brain Computer Interface (BCI) resembles a BMI in its wider definition, but in its narrower

- usage, it is a noninvasive BMI used to compensate for lost motor functions. An EEG-BCI uses such varied features as sensorimotor cortex μ rhythm, slow cortical potential, and the P300 to decode movement parameters including gaze direction and to control an interface, including controlling a computer mouse or selecting a character for communication (Birbaumer et al. 1999). Some BCIs are practical and/or commercially available. As rare examples of nonmedical BMI applications, inexpensive examples have been developed for gaming.
3. Neural prosthetics or BMIs in a narrow sense are an invasive BMIs used to compensate for lost or damaged motor functions. Proof of the concepts was demonstrated around 2000 in rodents and monkeys by pioneers such as Johan Wessberg (Wessberg et al. 2000), Andrew Schwartz (Taylor et al. 2002), and John Donoghue, and the technique was translated into human patients around 2005 (Hochberg et al. 2012). Invasive electrodes measure brain activity (several tens to a few hundred neurons), a decoder extracts the motor command information from neural signals, and finally an effector system is controlled by this extracted movement information. Users observe the results of the effector actions, and a loop is closed connecting the brain, the measurement system, the decoder and the effector, and the signals are returned to the brain. This is one of the most actively studied classes of BMI in the past 15 years. Subdural ECoG electrodes have recently attracted attention because they are more stable than the intracortical electrodes that are inevitably associated with scars. These less invasive BIM systems, which are not invasive to the brain itself, might be quite practical because decoding of the three-dimensional arm trajectory of monkeys using ECoG did not significantly deteriorate for a year or two (Chao et al. 2010), and ECoG-BMI can control a multi-joint robot arm and a hand system with exactly the same decoding parameters for over a week in humans (Yanagisawa et al. 2012).
 4. An EEG-BMI rehabilitation system is a noninvasive BMI used for the recovery of motor functions in stroke patients. This has opened up a quite promising newly-emerging BMI application field. With conventional rehabilitation protocols, useful (i.e., graspable) hands are restored in only 15% of stroke patients but that figure increases to around 80% with BMI rehabilitation. Pioneers Jun-ichi Ushiba and Meigen Liu recorded sensorimotor cortex μ rhythms from severe stroke patients whose extensor muscles could not even generate EMG, and decoded their movement intention based on the decrease in the μ power: event-related EEG desynchronization. When the decoder output was successful, both visual and kinesthetic feedback was given to patients via a robotic splint that extended their paralyzed wrists and fingers (Shindo et al. 2011).
 5. fMRI-decoded neurofeedback (DecNef) can be used as a noninvasive BMI system for treating abnormal central decision-making functions in psychiatric disorders (Kawato WFSBP Plenary talk 2013). Shibata, Watanabe, Sasaki, and Kawato developed DecNef, by means of which spatial activity patterns in a specific brain area can be noninvasively controlled through real-time fMRI neurofeedback (Shibata et al. 2011). First, a decoder is obtained that classifies BOLD signal patterns by visual attributes, emotional states or normal and pathological states in psychiatric disorders. In the induction stage, volunteers unconsciously control their brain activity so that a desirable pattern is produced while being guided by a real-time reward signal computed as the decoder output. Thus, three important elements of DecNef are decoding of information from fMRI brain activity, real-time neurofeedback of decoded information, and unconscious reinforcement learning by participants.
- In most BMIs, except the sensory substitution BMI, necessary brain information is first extracted from brain activity signals using a decoder. This information is transformed and fed back to users in some sensory modality with/without

reward signals, and finally BMI users learn to change their brain networks based on synaptic plasticity. In these three steps, computational neuroscience plays a critical role. For example, computational motor control models outline the neural prosthetics paradigm to record from many neurons, and use their firing frequencies to decode movement kinematics (Georgopoulos et al. 1982). Computational models also play important roles in non-invasive decoding algorithms (Miyawaki et al. 2008). Finally, neural operant conditioning in BMI users (Fetz 1969) can be understood from computational algorithms derived from supervised and reinforcement learning theories.

Definition

BrainMap is an online community database that archives the results of published functional and anatomical neuroimaging

experiments and their associated metadata (<http://brainmap.org>). Experimental results and metadata are archived into the database according to an expert-refined taxonomy developed to describe the experimental procedure employed in each publication within the database. Users may input publications and their associated neuroimaging results to the database using the *Scribe* application (<http://brainmap.org/scribe>) or search the database for publications of interest by applying filters in the *Sleuth* application (<http://brainmap.org/sleuth>). Coordinates of activation resulting from filtered searches may be downloaded and exported for further meta-analysis using the *GingerALE* application (<http://brainmap.org/ale>), which uses the activation likelihood estimation algorithm (ALE; Turkeltaub et al. 2002; Eickhoff et al. 2009).

Detailed Description

The advent of magnetic resonance imaging and positron emission tomography to acquire functional data of the human brain revolutionized the way scientists examined neural systems associated with cognition, perception, and action. Consequently, the volume of functional imaging publications has been increasing exponentially since in the early 1990s. Introduced over two decades ago, the BrainMap database (<http://brainmap.org>) was created to archive the results of the growing number of neuroimaging publications in a manner that leads to optimum accessibility (Fox et al. 1994; Laird et al. 2005, 2009). The BrainMap Project supports a database of functional neuroimaging experiments, as well as voxel-based morphometry database (VBM). Currently (as of October 2013), the BrainMap Functional Database includes 2336 publications, which reported the results of 11,103 functional activation experiments across a total of 45,188 subjects, while the BrainMap VBM Database includes 796 publications, which reported the results of 2444 structural neuroimaging experiments across a total of 55,222 subjects.

Standardized Coordinates

Neuroimaging experiments report locations of activation or deactivation as three-dimensional coordinates (x,y,z) in standard space. This practice allows for more precise quantitative localization of activation rather than qualitatively describing the structure associated with the activation. Due to the variability between each subjects' brain morphometry, activation coordinates are transformed into a common coordinate system for comparison across multiple subjects. The two best-known reference spaces for the human brain were developed by Talairach and Tournoux (Talairach and Tournoux 1988) and the Montreal Neurological Institute (MNI; Collins et al. 1994).

BrainMap Coding Scheme

A hierarchical taxonomy (Fig. 1) was developed for BrainMap such that the results of publications could be coded into the databases according to information about the subject population, task, imaging modality, or behavioral conditions associated with the experiment. The cataloguing of information in this manner not only provides consistent labeling of each experiment but also promotes rapid retrieval from the database. The publication is first coded according to citation information: publication journal and year, institution, and authors. Additional metadata fields include subject description (e.g., age, gender, handedness, ethnicity) and diagnosis (e.g., healthy or diseased), which are all fully described at the publication level. The published three-dimensional (x,y,z) coordinates extracted from statistical parametric images are archived from each experiment. Individual experiments are classified according to paradigm class, which describes the specific task being performed, and behavioral domain, which describes the cognitive construct being studied. The statistical contrasts of interest (e.g., "Task – Rest") producing the statistical parametric image are also archived at the experiment level (Fox and Lancaster 2002). When published coordinates are entered into the BrainMap database, MNI coordinates are

BrainMap, Fig. 1 Hierarchy of BrainMap coding scheme. Each publication consists of three levels of descriptors. At the highest level of each publication, general information about citation information, subjects, and summaries of the experimental design and results are

encoded. The condition level is composed of information about the behavioral stimulus, instructions, and response. The experiment level includes metadata fields that describe the contrasted brain images, with a tertiary level for archiving coordinate locations

transformed into Talairach space (Lancaster et al. 2007), and vice versa, providing the option for coordinate extraction in either coordinate system. Additionally, activation volume extent, statistical parameter, and significance level are all archived with each experiment.

Activation Likelihood Estimation

Since the results of neuroimaging experiments are typically reported as three-dimensional coordinates in standard space, the primary purpose of BrainMap is to support coordinate-based meta-analyses of functional and structural neuroimaging studies. Once a set of experimental results is identified in *Sleuth*, it is exported to *GingerALE* to perform a coordinate-based meta-analysis using the ALE algorithm. The ALE score determines the probability that a given location was reported active across the experiments selected. A permutation test has been implemented to test for statistical significance. The ALE method yields locations of consistent activation patterns across a set of similar neuroimaging experiments, which offers many benefits to simply reviewing the images on an experiment-by-experiment basis.

School of Medicine, University of Washington,
Seattle, USA

Definition

Brain stem motoneuron models are mathematical representations of the input–output properties of motoneurons located in the different motor nuclei of the brain stem.

Detailed Description

Several classes of mathematical models have been developed to describe the input–output properties of the resident motoneurons of the different motor nuclei of the brain stem (i.e., abducens, facial, hypoglossal, oculomotor, trigeminal, and trochlear). These models range in complexity from simple “black box” analytical models (Poliakov et al. 1997; Powers et al. 2005) to complete Hodgkin-Huxley-type ionic conductance-based models with reconstructed dendritic trees (Kulagina 2011). The choice of model type has been largely dictated by the question at hand, i.e., responses to synaptic inputs, intrinsic properties, aggregate or pool behavior, and contribution to neural circuits. In all variants, these models have proved extremely useful in the quantitative analysis of electrophysiological recordings from motoneurons and in the interpretation of studies of movements controlled by brain stem circuits (e.g., eye movements, breathing, and swallowing).

The analytical models typically involve recording the responses of brain stem motoneurons to electrical noise injected across the cell membrane through an intracellular electrode. The resultant spike trains are analyzed using systems identification techniques that typically yield two-stage cascade models, consisting of a linear input filter and a static nonlinearity (e.g., Poliakov

et al. 1997) or alternatively autoregressive-moving average models that differentiate the roles of input filtering and intrinsic spike-generating conductances in governing motoneuron discharge behavior (Powers et al. 2005). These models are useful in describing how brain stem motoneurons respond to the excitatory and inhibitory synaptic inputs they receive.

Partial Hodgkin-Huxley type ionic conductance-based models (Powers et al. 1999; Pierson et al. 2001; Purvis and Butera 2005) have been used to understand the mechanisms underlying spike-frequency adaptation of brain stem motoneurons and their responses to neuromodulators. More recently, complete Hodgkin-Huxley type ionic conductance-based models with reconstructed dendritic trees (Kulagina 2011) have been used to study how the topographic location of synaptic inputs and the presence of voltage-gated conductances in the dendritic membrane shape motoneuron discharge behavior.

To study the aggregate behavior of a pool of brain stem motoneurons, the individual cells are typically modeled as *integrate-and-fire* elements that begin discharging when a threshold input current is encountered and have their firing frequencies modulated in accord with a specified current-frequency transform. Such models may capture some of the variability inherent in a population of motoneurons by varying the threshold and current-frequency gains and are useful for determining the relative contributions of intrinsic electrical properties versus the distributions of specific synaptic input systems to motor output (Dean 1997). Integrate-and-fire representations of brain stem motoneurons are also useful in modeling brain stem circuits where the detailed physiology of the cellular elements is sublimated to the goal of understanding the behavior of the system (e.g., Scudder et al. 2002).

Brian Spiking Neural Network Simulator

Dan F. M. Goodman¹ and Romain Brette²

¹Department of Otology and Otolaryngology, Harvard Medical School, Boston, MA, USA

²Institut de la Vision, INSERM, CNRS, Université Pierre et Marie Curie, Paris, France

Definition

Brian (<http://briansimulator.org>) is an open source Python package for developing simulations of networks of spiking neurons (Goodman and Brette 2008, 2009). The design is aimed at minimizing users' development time, with execution speed as secondary goal. Users specify neuron and synapse models by giving their equations in standard mathematical form, create groups of

neurons, and connect them via synapses. The intent is to make the process as flexible as possible so that researchers are not restricted to using neuron and synapse models already built into the simulator. The entire simulator is written in Python, using the NumPy and SciPy numerical and scientific computing packages. Parts of the simulator can optionally be run using C++ code generated on the fly (Goodman 2010). Computationally, Brian uses vectorization techniques (Brette and Goodman 2011) so that for large numbers of neurons, execution speed is of the same order of magnitude as C++ code (Goodman and Brette 2008).

Detailed Description

Philosophy

The aim of Brian is to be, in order of priority:

1. Easy to learn, use, and understand.
2. Expressive and flexible.
3. Computationally efficient.

These choices were designed to both encourage correct and reproducible simulations and to minimize the development time of a simulation study as this is often much greater than the simulation time (Fig. 1).

Overview and Example

A simulation written with Brian is a Python module (script) that typically involves doing at least the following:

1. Import the Brian package.
2. Define parameters and equations.
3. Create groups of neurons with the NeuronGroup object.
4. Create synapses with the Connection or Synapses objects.
5. Specify variables to be recorded using SpikeMonitor and StateMonitor objects.
6. Run the simulation with the run function.
7. Analyze and plot the output.

Brian Spiking Neural Network Simulator,
Fig. 1 Example output of
 Brian simulator

The following example illustrates these steps
 (the output is shown below) (Fig. 1):

```
from brian import *
eqs = """
dv/dt = (ge+gi-(v+49*mV))/(20*ms) : volt
dge/dt = -ge/(5*ms) : volt
dgi/dt = -gi/(10*ms) : volt
"""
P = NeuronGroup(4000, eqs,
threshold='v>-50*mV', reset='v=-60*mV')
P.v = -60*mV+10*mV*rand(len(P))
Pe = P.subgroup(3200)
Pi = P.subgroup(800)
Ce = Connection(Pe, P, 'ge',
weight=1.62*mV, sparseness=0.02)
Ci = Connection(Pi, P, 'gi', weight=-9*mV, sparseness=0.02)
spikemon = SpikeMonitor(P)
statemon = StateMonitor(P, 'v',
record=range(4))
run(250*ms)
subplot(211)
raster_plot(spikemon)
```

```
subplot(212)
statemon.plot()
show()
```

Design

Brian is designed around equations: users specify neuron models in terms of differential equations in standard mathematical notation rather than using predefined neuron types, and event code such as threshold condition or reset code is also specified in terms of mathematical expressions or statements in standard notation. For example:

```
eqs = """
dv/dt = (ge+gi-(v+49*mV))/(20*ms) :
volt
dge/dt = -ge/(5*ms) : volt
dgi/dt = -gi/(10*ms) : volt
"""
```

The text after the colon on each line gives the units of the variable being defined (v, ge, gi here).

Equations are required to be dimensionally consistent.

Features

Brian has support for the following basic features:

- Define neuron models using arbitrary differential equations, threshold conditions, and reset codes.
- Define synaptic neuron models using arbitrary synaptic differential equations and propagation equations.
- Define parameter values using SI units.
- A library of standard neuron and synapse models.
- Record neuron activity, both spikes and traces.
- Plasticity (STDP, STP, arbitrary user-defined plasticity models).
- Gap junctions.
- Nonlinear synapses.

In addition, Brian comes with the following extension packages:

- Model Fitting (Rossant et al. [2010](#), [2011](#)). This package fits a user-specified neuron model to electrophysiological data. Fitting can be performed in parallel over multiple CPUs, multiple machines, and, if available, using graphics processing units (GPUs) for a speed improvement up to $60\times$.
- Brian Hears (Fontaine et al. [2011](#)). This package is for simple and efficient modeling of the auditory periphery. It consists of a base library for performing filter-based modeling, as well as implementations of many standard filter banks used in auditory periphery modeling.
- Electrophysiology. Models of electrodes and amplifiers, compensation, and analysis methods.

The online support for Brian consists of the following:

- Extensive documentation, including tutorials, examples, a manual, and a reference section.
- An online support mailing list, with feedback from developers and other users.

Definition

Bursting refers to patterns of neural activity consisting of episodes of relatively fast spiking separated by intervals of quiescence. Bursting neurons are ubiquitous in the nervous system and play important roles in the production of motor, sensory, and cognitive behaviors. Because bursting is the predominant mode of activity in *central pattern generator* (CPG) networks that underlie rhythmic motor activity, bursting neurons have been best characterized in invertebrate CPG networks. Bursting neurons fall into two classes, based on whether bursting is an intrinsic neuronal property, resulting solely from the interaction among ionic currents, or whether it is a network property, emerging from the interaction among ionic and synaptic currents.

Detailed Description

Introduction and Background

Bursting patterns consist of episodes of relatively fast spiking (bursts) separated by intervals of either quiescence or subthreshold activity such

as subthreshold oscillations (Kispersky et al. 2010; Malashchenko et al. 2011; Desroches et al. 2013). Bursting is ubiquitous in the nervous system and has been shown to play an important role in the generation of network rhythmic patterns (Nusbaum and Beenhakker 2002). Bursting neurons are of particular importance in rhythmically active CPG networks, which control the ongoing motor behaviors that underlie coordinated activity such as swimming, invertebrate heartbeat, feeding, and limbed locomotion (Friesen and Pearce 1993; Calabrese 1995; Calabrese et al. 1995; Marder and Calabrese 1996; Smarandache et al. 2009).

Extensive research into the mechanisms that generate network bursting activity and its role in motor behavior has been done in invertebrates (Calabrese 1995; Nusbaum and Beenhakker 2002; Selverston 2005). *Invertebrate CPG networks* are comprised of a relatively small number of neurons and, in many systems, the intrinsic properties of the participating neurons, and the network connectivity is well known. These networks produce multiple complex outputs that control similar behaviors as the much larger CPG networks of vertebrate animals (Marder and Calabrese 1996).

Bursting activity can be generated by individual neurons or through synaptic interactions within networks. *Endogenous bursting* in individual neurons emerges as the result of the interaction among participating ionic currents, often in the presence of tonic excitatory drive (Harris-Warrick and Flamm 1987; Guckenheimer et al. 1993). Endogenous bursting neurons are often pacemakers of the networks in which they are embedded, which rhythmically drive follower neurons (Selverston 2005). Bursting may also emerge as a network phenomenon through synaptic interactions of individual neurons that are not necessarily endogenous bursters (Selverston et al. 2009). In such networks, the rhythmic properties cannot be ascribed to any individual neuron but emerge as a result of synaptic organization. However, as described below, network bursting can also involve endogenous bursters.

While bursting is a stereotypical mode of neuronal activity, there are qualitatively different

types of bursting patterns that differ not only in the bursting attributes (e.g., burst frequency, number of spikes per burst, inter-burst interval, duty cycle) but also in the mechanisms that govern their generation. These mechanisms can be investigated from two different, but complementary, perspectives: membrane biophysics and dynamics. The *biophysical mechanisms* involve the participating ionic and synaptic currents and neuromodulators that interact to generate bursting activity. The *dynamical mechanisms* involve nonlinearities, time scales, and bifurcations that govern the initiation and termination of the bursts, the duration of the inter-burst intervals, and additional properties of the bursting patterns. There is no one-to-one correspondence between these two mechanisms. In fact, different sets of ionic currents can give rise to qualitatively similar bursting patterns by the same dynamical mechanism, and, similarly, the same sets of ionic currents can give rise to different bursting patterns. This article focuses on the dynamical mechanisms of bursting and some of the biophysical mechanisms underlying the dynamical behavior.

Endogenous Bursting in Individual Neurons

Bursting patterns can be considered as bursts of spiking activity in otherwise quiescent neurons or, alternatively, as persistent spiking which is periodically suppressed. These contrasting descriptions can be used to describe the main mechanistic features of bursting: the burst initiation and termination. Additionally, a complete description of bursting activity must include an analysis of spiking properties within a burst, in particular, what determines the intra-burst spike frequency, as well as the dynamical properties of the *inter-burst intervals* (IBIs).

Classification of Bursting Neurons Using Bifurcation Theory

A classification of mechanisms of spike initiation and termination has been described in terms of bifurcations of dynamical systems (Izhikevich 2000b, 2007). Bifurcations describe the qualitative structural changes in the dynamics of the system. The dynamical systems analysis of neuron and network dynamics is based on the

assumption that the output of the system is the solution of a set of differential equations, based on the biophysical properties of the neurons and their synaptic connections. The number of variables in the differential equation is often referred to as the dimension of the system. From a mathematical viewpoint, these equations result in a stable solution trajectory (not necessarily solvable explicitly) that describe the time-dependent changes in the dynamical properties of the neurons, including the voltage trajectories. Using dynamical systems methods, these equations can be analyzed, often in a reduced form, by exploring the transitions between fast and slow kinetics. The *resting state* of a neuron, for example, may correspond to a stable *equilibrium* point of the dynamical systems equations. *Repetitive spiking*, in contrast, corresponds to a stable *periodic orbit* (limit cycle).

Dynamical systems often evolve in multiple time scales. For instance, the rest state of a neuron can, in a slow time scale, gradually drift to a more depolarized voltage and then suddenly transition to a spiking state. In the fast time scale, these transitions appear as sudden changes in the geometric properties of the system: a stable fixed point (rest state) suddenly changes into an unstable one, and a stable periodic orbit (spiking) appears. These transitions reflect the bifurcations of the underlying dynamical system. A thorough study of the bifurcations underlying the generation and termination of bursting activity can be found in Izhikevich (2000b).

In the classification of bursting dynamics, the underlying bifurcations of the fast dynamics can be used to describe the overall burst structure. For instance, a saddle-node (SN) bifurcation and a homoclinic (HOM) bifurcation govern burst initiation and termination, respectively, in *square-wave* bursters (Fig. 1). In contrast, both burst initiation and termination in *parabolic* bursters (Fig. 2) are governed by saddle-node on an invariant circle (SNIC) bifurcation (Rinzel and Lee 1987; Butera et al. 1996; Rinzel and Ermentrout 1998). *Elliptic* bursters involve a subcritical Andronov–Hopf bifurcation (**sub-AH**) and an SN bifurcation for burst initiation and termination, respectively (Izhikevich 2000a) (Fig. 4). To a large extent, these bifurcations also govern the

Bursting in Neurons and Small Networks, Fig. 1 *Square-wave bursting in the modified Morris-Lecar model.* (a) Slow negative feedback via calcium accumulates during the burst and slowly decays during the silent phase. The slow accumulation of calcium activates $I_{K(Ca)}$, which subsequently terminates the burst.

Calcium concentration is governed by $Ca' = \epsilon(-\mu g_{Ca} m \infty(V)(V - E_{Ca}))$, $Ca_0 = 10$, $\epsilon = 0.005$, $\mu = 0.2$. (b) Bifurcation diagram showing the region of bistability and bursting. The bifurcation parameter z is a function of calcium. Arrows indicate the direction of the change in z during silent and active phases of bursting

Bursting in Neurons and Small Networks, Fig. 2 *Parabolic bursting in the modified Morris-Lecar model.* Model is the same as in Fig. 1 with an additional slow variable s to generate the underlying slow oscillation: $I_{Ca,s} = g_{Ca,s}(V - E_{Ca})$. (a) Projection of the bursting trajectory onto the slow-variable plane. Direction of movement is indicated with arrows. The straight line

represents the boundary between equilibria and oscillation for the fast subsystem when the slow variables are fixed; it is where the SNIC bifurcation occurs. Below the low-voltage steady state is the only fast subsystem attractor (silent phase), whereas above this curve there is an oscillation of the fast subsystem (spiking). (b) Time course of parabolic bursting

dynamics of both the intra-burst spike frequency and the IBIs, for example, the shape and amplitude of spikes, spike-frequency adaptation, and bistability (Cymbalyuk et al. 2002).

From a dynamical systems viewpoint, a simple model that is able to generate oscillatory behavior is two-dimensional and involves the interaction of voltage and a recovery variable. Voltage increases due to a positive feedback effect on a relatively fast time scale, typically generated by calcium or sodium. The recovery variable opposes the changes in voltage on a slower time scale and, in biophysical models, corresponds to a state

variable of a voltage-gated ionic current such as a potassium current. Although the classical Hodgkin-Huxley model is four-dimensional (Hodgkin and Huxley 1952), the spiking behavior in this model can be reduced to a two-dimensional model (Kepler et al. 1992) without losing significant information.

A simple way to produce bursting activity in a model is to use a two-dimensional system that produces spiking and add one or two slow variables that modulate the spiking activity. The dynamical variables that make up a bursting neuron can then be separated into two subgroups: fast

(if they evolve on the time scale of a spike) and slow (if they evolve on the time scale of a burst, roughly determined by the IBI), thus giving these models their name, fast–slow bursters. The bursting model can then be written in the following form:

$$X' = F(X, Y)$$

$$Y' = \mu G(X, Y),$$

where X is a vector of at least 2 fast variables for repetitive spiking. Y is a vector of slow variables that modulates fast spiking. The small parameter $\mu \ll 1$ is a ratio of fast–slow time scales. To determine the type of bursting activity that the dynamical system will exhibit, the slow variable Y is treated as a constant parameter in the fast subsystem equation $X' = F(X, Y)$. The parameter Y is used to determine the bifurcations in the geometric properties of the fast subsystem which correspond to the transitions at the burst onset and termination.

The number of slow variables necessary to produce bursting in a model neuron depends on the underlying generic burst mechanisms that involve additional specific mechanisms of burst initiation and termination. A bursting neuron can be driven by one of the two generic mechanisms: a *hysteresis loop* such as in the square-wave burster (Fig. 1), or a *slow wave*, such as in the parabolic burster (Fig. 2). Hysteresis loop refers to the existence of bistable dynamics in the fast subsystem: if the slow variables are kept fixed at a constant value (within some range), the fast subsystem will exhibit two attractors (a stable equilibrium point and a periodic orbit) simultaneously. Hysteresis-loop bursting requires only one slow variable, resulting in three total variables as a minimal model for bursting. The slow variable allows the bistable fast subsystem to transition between its two stable states in either of two ways (Rinzel and Ermentrout 1998). For example, when the trajectory is near the stable fixed point of the fast subsystem, the slow variable grows until this fixed point becomes unstable (through a fast subsystem bifurcation) and the trajectory transitions to the stable periodic orbit. The slow variable then

decays until the stable periodic orbit vanishes or becomes unstable (again through a fast subsystem bifurcation) and the trajectory transitions back to the stable fixed point and the cycle repeats.

In contrast, if the fast subsystem is monostable such as in the parabolic burster (Fig. 2), two slow variables will be necessary to generate bursting activity, resulting in a total of four variables for a minimal model of bursting. In this case, the slow subsystem requires two variables and exhibits an autonomous limit cycle attractor without feedback from voltage changes in the fast subsystem. The neuron bursts because the fast subsystem is driven periodically through SNIC bifurcations.

In what follows, we will think of a fast–slow burster as a slow system driving the fast system through various bifurcations that govern the initiation and termination of bursting activity. There are 16 possible pairs of bifurcations in hysteresis-loop bursters and 8 possible pairs of bifurcations in slow-wave bursters (Izhikevich 2000b). Each one of these bifurcations corresponds to a different topological bursting mode. Although not all these bifurcations have been found in biological neurons, this description has proved to be insightful. We discuss some of them in detail below (for additional information, see Izhikevich (2000b)).

One of the 8 slow-wave bursters can arise from a pair of SNIC bifurcations (both burst onset and termination) and is also known as the circle–circle or parabolic bursting (Fig. 2). The topological type of the hysteresis-loop burster depends on whether the fast system is close to either an SN-homoclinic orbit or a Bautin bifurcation (Figs. 3 and 4). For instance, one of the 16 possible hysteresis-loop bursters involves sub-AH/fold combination of bifurcations to obtain an elliptic burster (Figs. 4 and 5).

The pairs of bifurcations that determine the initiation and termination of a burst can also be used to classify bursting neurons based on their intra-burst spike-frequency content. If the burst onset is through a SNIC bifurcation, the burst shows a progressive increase in spike frequency. If the burst termination is through a homoclinic orbit bifurcation, there is spike-frequency adaptation (a progressive lengthening of inter-spike intervals (ISIs)) near the end of the burst. This is

Bursting in Neurons and Small Networks, Fig. 3 Pairs of bifurcations in fast-slow hysteresis bursters with the fast subsystem near a saddle-node homoclinic orbit (SN-HOM) bifurcation. (a) Bifurcation diagram showing changes in the geometry of the fast subsystem as parameters are varied. (b) A system near

such an SN-HOM bifurcation may exhibit four different types of fast-slow bursting. Traversing from the red region to the green region leads to square-wave bursting in which burst initiation is through the fold (or SN) bifurcation and the burst termination is through a homoclinic orbit bifurcation

Bursting in Neurons and Small Networks, Fig. 4 Pairs of bifurcations in fast-slow hysteresis bursters with the fast subsystem near a Bautin bifurcation. (a) Bifurcation diagram showing changes in the geometry of the fast subsystem as parameters a and b in the topological normal form $z' = (a + i\omega) + b|z|^2 - z|z|^4$ are varied. When the system is near a Bautin (or Andronov-Hopf) bifurcation it may exhibit four types of bursting when the bifurcation parameters a and

b change. In the upper two quadrants, the bifurcation of the rest state takes place via the super-AH and in the lower two quadrants via the sub-AH bifurcation. (b) Four possible topological types of bursting with different bifurcations of the rest and spiking states. Traversing from the red region to the green region leads to elliptic bursting in which the burst initiation is through the sub-AH bifurcation and the burst termination is through the fold bifurcation

a prevalent feature in invertebrate bursting neurons. Guckenheimer et al. (1997) studied the scaling properties of ISIs at transitions associated with

a homoclinic bifurcation corresponding to the transition from spiking to quiescence. The homoclinic orbit bifurcation results in a spike frequency

Bursting in Neurons and Small Networks, Fig. 5 *Elliptic bursting in the Morris-Lecar model (variables V and w) with an additional $I_{K(Ca)}$. Green curves are nullclines $V' = 0$ and $w' = 0$ of the fast subsystem. As the neuron transitions from silence to bursting*

and back again, there is a clear sequence of changes in the geometry of the phase plane of the fast subsystem. These changes correspond to bifurcations. In the elliptic burster, burst initiation is through the sub-AH bifurcation, and burst termination is through the fold (or SN) bifurcation

that decreases as a function of the distance to the saddle. The proximity of homoclinic and a sub-AH bifurcation was used to explain the phenomenon of spike-frequency adaptation. The slow adaptation variable will cause the trajectories of the fast system to track a family of stable periodic orbits until the homoclinic bifurcation is reached, after which they become quiescent (Guckenheimer et al. 1997).

Models of Bursting Neurons

Bursting in neurons is a dynamical mechanism generated by the interplay of different types of ionic currents. There is not a one-to-one mapping between the sets of ionic currents and the stereotypical type of bursting patterns. Bursting mechanisms have been studied using biophysical

(conductance-based) models, which include a detailed description of the participating currents, or reduced models, capturing stereotypical bursting patterns in a relatively simple way, but lacking any correspondence to the underlying biophysics. Below, we briefly describe these two approaches with a special emphasis on biophysical models related to invertebrate systems.

Reduced Models

The simplest mechanism to generate bursting activity consists of a sinusoidally forced integrate-and-fire (IF) model (Lapicque 1907) where the subthreshold dynamics are linear. The sinusoidal input brings voltage above threshold for a portion of its period, thus causing persistent firing during an interval within this period and silence outside

it. This mechanism can be extended to include models with two- and three-dimensional linear subthreshold dynamics (with or without intrinsic subthreshold oscillations) and the quadratic integrate-and-fire models (Feng 2001). While the subthreshold dynamics in these models can be in principle connected to the biophysical properties of neurons, the spike initiation and termination mechanisms are ad hoc.

The integrate-and-fire-or-burst (IFB) (Smith et al. 2000) model is a generalization of the IF model to include an additional slow variable representing the de-inactivation of a simplified T-type calcium current (I_T) with instantaneous activation. The subthreshold dynamics are, therefore, two-dimensional. This additional current endows the model with the ability to exhibit post-inhibitory rebound (PIR). This model is able to generate bursts of activity when voltage is hyperpolarized enough to de-inactivate I_T . Since the threshold for de-inactivation is more depolarized than the resting voltage, the neuron can respond to a brief input with a burst of spikes. However, the intrinsic dynamics of the model does not produce enough hyperpolarization, and so periodic bursting requires an additional sinusoidal input current.

The FitzHugh–Rinzel (FHR) model (Rinzel 1986) is a three-dimensional generalization of the (two-dimensional) FitzHugh–Nagumo (FHN) model (Fitzhugh 1961; Nagumo et al. 1962; Fitzhugh 1969). The classical FHN forms the fast subsystem, which, to first approximation, produces oscillations when the (unstable) fixed point is located in the middle branch of the cubic V -nullcline. The transition from a stable fixed point to a stable limit cycle occurs through an Andronov–Hopf bifurcation as the tonic (DC) current is increased. In the FHR model, this control parameter is substituted by a slow variable, which governs the generation of elliptic bursting. Modifications to this model could, in principle, generate bursting activity by other mechanisms.

The Hindmarsh–Rose (HR) model (Hindmarsh and Rose 1984; Hindmarsh and Cornelius 2005) is also three-dimensional and slightly more complex than the FHR model. In contrast to the FHN

model, the fast subsystem of the HR model has a quadratic recovery-like nullcline that creates extra equilibrium points. This produces bistability through proximity to a saddle-node homoclinic orbit bifurcation. A slow adaptation variable provides the necessary negative feedback to generate square-wave bursting.

Minimal (Phenomenological) Biophysical Models

The two-dimensional version of the Morris–Lecar (ML) model (Rinzel and Ermentrout 1998) describes the generation of oscillatory activity as the result of the interaction of a non-inactivating calcium current with instantaneous activation and a delayed-rectifier potassium current. The mechanisms responsible for the generation of oscillations include the Andronov–Hopf and SNIC bifurcations and depend on the parameters describing the activation/inactivation curves and voltage-dependent time scales. The parameters of the basic ML model can be adjusted to simulate the envelope of bursting waveforms, which has been carried out in modeling the AB–PD neurons of the pyloric pacemaker in the crustacean stomatogastric ganglion (STG) (Skinner et al. 1994; Kopell et al. 1998). The substitution of a biophysical parameter (I_{app}) by a slow variable endows the ML model with the ability to generate bursting activity. One example is the bursting patterns generated by adding a calcium-activated K^+ current, $I_{K(Ca)}$:

$$I_{K(Ca)} = \tilde{g}_{K(Ca)} \left(\frac{Ca^p}{Ca^p + 1} \right) (V - E_K)$$

The modified ML model for bursting becomes

$$\frac{dV}{dt} = - \frac{(I_{Ca} + I_K + I_L + I_{K(Ca)})}{C}$$

$$\frac{dw}{dt} = \frac{\lambda[w_\infty - w]}{\tau(V)}$$

$$\frac{dCa}{dt} = \varepsilon(-\mu I_{Ca} - Ca)$$

As the calcium concentration varies, the system may become bistable so that the fast

subsystem can periodically switch back and forth between repetitive spiking and resting, thus producing bursting. The modified ML model is able to produce either *square-wave* or *elliptic* bursting patterns by changing parameter values that alters the type of bistability in the fast subsystem. Burst initiation by a sub-AH bifurcation produces an elliptic burster, whereas burst initiation by a saddle-node bifurcation produces a square-wave burster. To obtain the slow-wave oscillation underlying *parabolic* bursting in the ML model, the addition of one more variable is required to provide a slow positive feedback that counteracts the slow negative feedback of $I_{K(Ca)}$.

Biophysical Properties of Bursting Neurons

Bursting in neurons arises from a complex interaction between many ionic currents, where the actual ionic mechanisms may vary between different bursting neuron types. In most cases, bursting oscillations involve the presence of a slow inward ionic current. The current–voltage (IV) relationship of this inward current includes a negative slope region and results in an inverted bell-shaped structure which allows the inward current to become active regeneratively. Such currents include the persistent Na^+ current (I_{Nap}) and low-threshold inactivating calcium currents (I_{Ca}). Such currents can work together with other currents such as the slow calcium-activated non-selective cation current (I_{CAN}) and the hyperpolarization-activated inward current (I_h) to depolarize the membrane potential and produce a burst of action potentials. The activation of these inward currents, which leads to a burst of spikes, is counteracted by the slow activation of voltage- and calcium-dependent outward currents which terminate the burst. Moreover, some inward currents, such as the T-type calcium current, inactivate upon depolarization of the membrane potential, and this inactivation may also contribute to the termination of the burst.

Often neurons that do not burst in isolation can produce bursting activity in a network (as described in the next section). The pyloric network LP neuron does not burst endogenously but, in response to inhibitory input, can produce post-inhibitory rebound and plateau potentials

that support a burst of action potentials. These properties were described in detailed biophysical models of this neuron, first in a single-compartment model (Buchholtz et al. 1992; Golowasch et al. 1992) and, more recently, in a multi-compartment model that was used to explore how different ionic conductance levels can produce similar bursting output in this neuron (Taylor et al. 2009). In the biological network, the LP neuron receives periodic inhibition from the pacemaker neurons AB and PD which result in the production of bursting activity out of phase with the pacemaker bursts. Plateau potential generation is supported by a similar set of ionic currents as those that underlie bursting activity. For example, the low-threshold slowly inactivating I_{Ca} is substantially inactive at rest, but inactivation can be removed upon inhibitory input, thus promoting the plateau potential, often together with a burst of spikes. Zhang et al. (1995) showed that, in the dorsal gastric (DG) motor neuron of the STG, I_{CAN} , which is activated by calcium but is carried by Na^+ and K^+ , can underlie the plateau potential that results in a long after-depolarization and contributes to burst firing. The current usually acts alongside a low-threshold I_{Ca} , and the dynamical interaction can cause a strong regenerative current that supports plateau potentials.

The pacemaker AB neuron of the crustacean pyloric network is an endogenous burster whose bursting activity depends on the presence of extrinsic neuromodulatory inputs (Hooper and Marder 1987). Early attempts to dissect the ionic mechanism underlying endogenous bursting involved a plateau potential which is initiated and maintained by I_{Nap} and I_{Ca} and terminated by $I_{K(Ca)}$ (Gola and Selverston 1981). Burst frequency in AB is strongly dependent on calcium entry because burst frequency decreases with calcium entry and higher calcium entry results in a larger potassium-mediated post-burst hyperpolarization. The AB neuron employs different mechanisms for bursting under a variety of modulatory conditions (Harris-Warrick and Flamm 1987). A modeling analysis of the AB neuron bursting activity examined the mechanisms that generate and control bursting in this neuron and its electrically coupled partner, the PD neuron (Soto-

Trevino et al. 2005). This model demonstrated that the bursting in the AB neuron was crucially dependent on the modulator-activated inward current $I_{M\bar{D}}$, and, as discussed in the next section, the PD neuron greatly influences the duty cycle and dynamical range of bursting frequency in the pacemaker group.

Bursting can also occur solely due to the slow inactivation of I_{Ca} without the need for bistability. Two examples of ionic mechanisms underlying burst firing are the R15 neuron, located in the abdominal ganglion of the mollusk *Aplysia californica*, and the lobster cardiac ganglion interneurons. The essential ingredients for bursting in the R15 neuron are the negative slope region of I_{Ca} that determines the burst onset, together with the calcium-dependent inactivation of this current, which terminates the burst (Adams and Levitan 1985; Kramer and Zucker 1985). A biophysical model of the R15 neuron showed that $I_{K(Ca)}$ and I_{CAN} are not necessary for producing the parabolic-like bursting in this neuron (Canavier et al. 1991). This modeling study also demonstrated the presence of slow oscillations in the absence of action potentials, supporting the parabolic structure (Fig. 2) of the bursting. The parabolic nature of the R15 bursting was further supported by the nonuniform intra-burst spike frequency, even in the absence of $I_{K(Ca)}$. Similar to the R15 neuron, the lobster cardiac ganglion interneurons respond to a steady depolarizing input with slow-wave oscillations called driver potentials. These driver potentials are mediated by slow activation and calcium-dependent inactivation of an I_{Ca} (Tazaki and Cooke 1990).

Bursting in Networks of Neurons

Principles Underlying Rhythmic Bursting in Networks

CPG oscillations can arise either from pacemaker neuron activity or as a network property. In pacemaker-driven networks, one or more neurons can be identified that produce bursting oscillations even when synaptically isolated from the network. The rhythm generated by these pacemaker neurons is then propagated to the network through synaptic interactions. In pacemaker-driven

networks, the properties of the pacemaker neurons are the primary determinant of the rhythm frequency. In contrast to pacemaker-driven CPG networks, in other CPG networks, the rhythmic pattern generation is controlled by subnetworks of neurons and thus emerges as a network property. Although network-driven CPGs may also include endogenously bursting neurons, the network frequency in these CPGs is primarily determined by parameters that control the activity of the rhythm-generating subnetwork.

Half-Center Oscillators

Early studies of locomotion in cats by Graham Brown led him to suggest that the alternating activity of flexor and extensor muscles is controlled by a network of two neuron populations in the spinal cord, each of which inhibits the other to produce antiphase alternating activity. He termed these putative central networks that produce antiphase motor activity half-center oscillators (HCOs) (Graham Brown 1911). Later studies have found reciprocal inhibition to be a prevalent feature of CPG networks in both vertebrates and invertebrates (Marder and Calabrese 1996). In invertebrate CPGs, HCOs are often comprised of two neurons coupled through reciprocal inhibition. The two-cell HCOs provide the simplest network mechanism that is capable of generating stable bursts of alternating activity. Alternating bursting oscillations can arise in HCOs as an emergent network property even when the individual component neurons are not oscillatory (Wang and Rinzel 1992). When the HCO is composed of endogenous bursting neurons, mutual inhibition acts to stabilize the burst period, and bursting occurs over a much wider range of biophysical parameters (Cymbalyuk et al. 2002). Examples of CPG networks whose rhythm-generating mechanism involves HCOs include the CPGs that control leech swimming and heartbeat (segmental oscillators), the crustacean gastric mill network, and the swim networks in lamprey and the gastropod mollusk *Tritonia*.

Antiphase patterns in HCOs can be generated by various mechanisms that have been classified according to whether intrinsic or synaptic properties are involved and whether the inhibited cell

transitions to the bursting regime before or after the termination of inhibition by the other cell. The terms *intrinsic release/escape* and *synaptic release/escape* (Wang and Rinzel 1992; Skinner et al. 1994) have been used to describe these mechanisms. *Intrinsic release* refers to the inhibited cell initiating a burst only when the free cell reaches the end of its burst and turns off inhibition. *Intrinsic escape* refers to the inhibited neuron generating a burst while it is still inhibited and subsequently shutting off the free neuron. Post-inhibitory rebound (PIR) has been shown to initiate the inhibited cell burst when the neuron is non-oscillatory (Wang and Rinzel 1992), although it has also been shown that a PIR-like current is not required to generate oscillations in HCOs composed of non-oscillatory neurons (Skinner et al. 1994). *Synaptic release* refers to the free neuron membrane potential falling below the synaptic threshold, thereby allowing the inhibited neuron to transition to a burst. In contrast, *synaptic escape* refers to the inhibited cell membrane potential depolarizing and crossing a (low) synaptic threshold, thereby inhibiting the free cell. The description of these mechanisms assumes rather restrictive conditions: (i) synapses with well-defined synaptic thresholds and no dynamics and (ii) HCOs that are active in the relaxation regime (very fast transitions for burst onset and termination). When these conditions are relaxed, antiphase patterns may emerge as a result of combinations of escape and release such as in the HCO of the leech heartbeat timing network (Nadim et al. 1995a).

The Role of Electrical Coupling

Computational studies of electrical coupling have provided much insight into the role of gap junctions in networks especially because an inability to cleanly block gap junctions has led to a paucity of experimental data. Electrical coupling is known to promote synchrony in a network. However, more complex and nonintuitive behaviors can arise from electrically coupled networks (Sherman and Rinzel 1992; Chow and Kopell 2000). Electrical coupling between an oscillatory and a bistable neuron can result in a wide variety of behaviors that depend on both the intrinsic

biophysical properties and the coupling strengths (Sherman and Rinzel 1992; Kopell et al. 1998). Weak coupling between two identical neurons can induce antiphase oscillation, which extends far beyond the parameter range for oscillation in single neurons, thus making for a more robust oscillator (Sherman and Rinzel 1992). Electrical coupling can also produce oscillatory activity when neurons that are silent in isolation are coupled through gap junctions (Sherman and Rinzel 1992; Manor et al. 1997).

The properties of a non-oscillatory neuron can regulate features such as frequency and amplitude of a bursting neuron to which it is electrically coupled. However, the influence of a non-oscillatory through gap junctions on oscillations of a bursting neuron can be nonintuitive (Kepler et al. 1990). Kepler et al. examined the effect of the PD neuron on the bursting activity of the AB neuron and showed that the electrical coupling between these neurons can serve to either increase or decrease the oscillation frequency depending on the voltage waveform of the bursting AB neuron. This effect was further explored through a mathematical analysis of the effect of a bistable neuron coupled to an oscillatory neuron which showed how the network frequency is influenced by the relative voltages of the bistable neuron compared to the voltage range of oscillations in the oscillatory neuron. This influence is dependent on the strength of coupling in a nonlinear manner (Kopell et al. 1998). Using ML neurons in the relaxation-oscillation regime, the authors showed how the electrical coupling can “pin” the voltage trajectory to the low or high branches of the voltage nullcline than compared to the uncoupled oscillator, thus changing the frequency and shape of the oscillations. Unexpectedly, a coupling with higher strength may not necessarily be more effective at influencing the frequency.

The effect of electrical coupling has also been investigated in biophysically realistic model neurons. In the STG pyloric network, for example, electrical coupling between the AB and PD pacemaker neurons causes these neurons to fire in synchrony. Of the two, AB is the only neuron that is capable of endogenous bursting. These two neurons, by virtue of their electrical coupling,

fire burst in phase over a wide range of frequencies (Soto-Trevino et al. 2005). The frequency of the isolated AB neuron can be greater than 2 Hz but limited to 1 Hz in the intact network, i.e., when coupled to the PD neuron (Hooper and Marder 1987). Previous modeling work using reduced models had suggested that the role of the PD neuron in this coupled pair is to regulate the network frequency (Hooper and Marder 1987; Kepler et al. 1990; Abbott et al. 1991). The Soto-Trevino et al. multi-compartment model of the AB–PD pacemaker ensemble demonstrated that increasing the coupling strength caused the slow-wave oscillation and spikes to become near synchronized (Soto-Trevino et al. 2005). For large coupling strengths, the non-oscillatory PD neuron transitioned from tonic spiking to large-amplitude bursting. Coupling of the PD to the AB neuron also increased the frequency of AB oscillation compared to the isolated AB frequency. Thus, the network possesses a way to regulate bursting oscillations that is anatomically separate from the mechanism of the generation of the bursting.

Segmented Networks of Bursting Neurons

In segmented animals, locomotion and other motor functions often require that the movement of different body parts maintain a constant phase relative to adjacent parts, despite changes in frequency. In crayfish and leech, swimming is controlled by the coordinated bursting activity of distributed CPGs in which the undulatory movements appear as a traveling wave. This traveling wave is generated by segmental oscillators with intersegmental phase lags. The neural basis that accounts for the stable intersegmental phase differences has been modeled as linear chains of weakly coupled oscillators (Friesen and Pearce 1993; Skinner et al. 1997; Jones et al. 2003).

The crayfish swimmeret system is a good example of intersegmental coordination. The bursting activity that drives the alternating power and return strokes of individual swimmerets on each segment is driven by a local CPG module. Bursts of impulses in coordinating interneurons control the relative timings of intersegmental bursts and result in a very stable anterior-to-posterior phase progression of bursts that differ

in phase by about 90° between adjacent segments (Smarandache et al. 2009; Mulloney and Smarandache 2010).

Swimming in the leech is also involves intersegmental coordination and is characterized by a wave that travels rostral-caudally along the animal. The crests and troughs are produced by antiphase contractions in dorsal and ventral longitudinal muscles in body wall segments. Intersegmental phase lag in body movement is stable at $\sim 20^\circ$ (Friesen and Pearce 1993). Phase differences are also observed between segmental oscillators in the timing network of the leech heartbeat CPG.

The leech heartbeat pattern is bilaterally asymmetric: on one side, a rostral-caudal wave of muscle contractions causes the peristaltic flow of blood through the heart tube, whereas, on the contralateral side, all segments contract in synchrony. This asymmetric activity switches after 20–50 cycles. Rhythmic activity of the leech heartbeat CPG arises independently in pairs of HCOs located in the third and fourth ganglia (Nadim et al. 1995b; Hill et al. 2002). Rhythmic bursting arises from mutual inhibitory connections between two such neurons. These rhythm-generating subnetworks are coupled via coordinating interneurons from other segmental ganglia to produce a stable phase difference in the range 15–20% (Hill et al. 2002).

The theory of weakly coupled oscillators (Schwemmer and Lewis 2012) has been used to understand intersegmental coordination. This theory is used to predict phase differences between segmental oscillators under a mathematically described assumption of weak coupling. A chain of such oscillators with nearest-neighbor coupling can support a constant-speed traveling wave. The weak coupling implies that the intrinsic dynamics are dominant, so that the perturbed system remains close to the limit cycle and the coupling only affects the speed with which the neuron moves around its limit cycle. This limit cycle represents the oscillatory spiking activity in the case of a tonic spiking neuron or the slow-wave oscillations in the case of a bursting neuron (as in Jones et al. 2003). The dynamics of each neuron can be reduced to a single-phase equation that

describes the phase of the neuron in the limit cycle. This allows for the construction of phase models to investigate the pattern of timings of individual elements in a network and the collective properties of the system.

The key to reducing a high-dimensional model and exploiting the form of the phase equations is the computation of the phase interaction function H (Ermentrout and Kopell 1991; Schwemmer and Lewis 2012), which reduces the interaction between the oscillators to a function of their phase difference $\Delta\varphi$. Methods of singular perturbation theory can often be used as an approach for deriving the interaction function H (Hoppensteadt and Izhikevich 1997). The essential step in deriving H is the infinitesimal phase response curve (iPRC) and its relation to the solution to the adjoint equation. The iPRC quantifies the normalized shift due to an infinitesimally small perturbation delivered at any given phase on the limit cycle so that the oscillator responds in a linear fashion.

In the crayfish swimmeret system, the coupling functions H have been approximated experimentally to understand how multiple oscillator elements coordinate their activity to produce wavelike activity representative of swimmeret locomotion (Skinner et al. 1997; Jones et al. 2003). In this case, the iPRC was used to approximate the H function and the zeroes of the G function coupling two modules for a model containing two ascending and one descending connection predicted a stable phase difference of 90° . A good agreement with the experimental data showed that the effects of both excitatory and inhibitory ascending connections combine to promote a Stable 90° phase lag between power stroke neuron bursts in neighboring ganglia.

Different strategies are used to achieve the appropriate phase differences between neighboring segments. Phase differences generated by asymmetries in the coupling between segmental oscillators, where ascending and descending interneurons vary in strength and sign (Skinner and Mulloney 1998; Smarandache et al. 2009). On the other hand, the excitability gradient hypothesis states that phase differences arise from the intrinsic frequency or excitability

differences between segmental oscillators (Grillner et al. 1993). In the crayfish swimmeret CPG, stable phase differences arise due to the combined effect of excitation and inhibition from ascending and descending coordinating neurons (Jones et al. 2003). In contrast, in the leech heart-beat timing network, a stable phase difference seems to arise from coupling between segmental oscillators of different inherent frequencies. When two segmental oscillators with different intrinsic frequencies were coupled in a model network, the faster one dominated the network frequency and led in phase. The phase difference was directly correlated with the difference in periods (Hill et al. 2002). This phase difference arises because the faster segmental oscillator bursts before the slower one and thereby terminates the activity of the shared coordinating interneuron. There is a brief time in each cycle when the slower segmental oscillator is relieved of inhibition from coordinating interneurons before the faster segmental oscillator ends its burst. Thus, the slow segmental oscillator can be entrained by the fast segmental oscillator through the indirect action of the coordinating interneuron.

Summary

Bursting is a ubiquitous property of neurons in many systems. Bursting in single neurons often results from the interaction of voltage-gated ion channels at various time scales. Bursting can be modeled at different levels of complexity, from abstract reduced models to minimal two- and three-dimensional models and biophysical realistic conductance-based models, often with good agreement with the experimental activity. A bursting neuron is often described by a system of ordinary differential equations operating at two different time scales, also called fast-slow bursters. The different types of bursting in such systems have been classified according to dynamical systems theory in terms of the transitions between the silent and spiking states. The hysteresis-loop bursting is the simplest form of bursting that requires only one slow variable in

addition to the fast subsystem that can operate in two stable states: quiescent or tonic spiking. On the other hand, without such fast bistable dynamics, the slow-wave oscillation must be generated independent of the fast spiking and requires at least two slow variables. The classification of different bursting mechanisms is usually done by describing the transitions between the silent and active phases of bursting using bifurcation theory analysis of dynamical systems.

Many oscillatory networks include bursting neurons that are not endogenous bursters. These neurons respond to synaptic input with bursts of spikes that are generated by the activation of regenerative or hyperpolarization-activated inward currents. Even in a two-cell network, the coupling of a bursting neuron to a non-oscillatory neuron can result in phase-locked bursting. In this case, the properties of the non-oscillatory neuron can influence the network frequency and the oscillation amplitude, often in unexpected ways. Electrical coupling of a non-oscillatory neuron to a bursting neuron, for example, can lead to faster or slower bursting oscillations. On the other hand, reciprocally inhibitory coupling can lead to either alternating or synchronized oscillations. In larger networks of bursting neurons, such as those involved in the control of locomotion, the oscillatory activity can be analyzed as a chain of coupled oscillators. These oscillators often represent the bursting activity of the locomotor networks as recorded from the segments of the spinal cord. The theory of weakly coupled oscillators provides a powerful tool for the understanding of how phase-locked oscillations arise in chains of segmental oscillators and can be used to predict which cellular or synaptic parameters control the frequency of the network and the relative phase of the segmental oscillators.

Cable Equation

William R. Holmes
Department of Biological Sciences, Ohio
University, Athens, OH, USA

Definition

The cable equation is a mathematical equation derived from a circuit model of the membrane and its intracellular and extracellular space to provide a quantitative description of current flow and voltage change both within and between neurons, allowing a quantitative and qualitative understanding of how neurons function.

Detailed Description

Brief History of Cable Theory in Neuroscience

The origins of cable theory date back to 1855 to work by Lord (William Thomson) Kelvin, “On the Theory of the Electric Telegraph,” which provided the mathematical theory necessary for laying the transatlantic telegraph cable. The utility of this work for neuroscience, however, was not recognized until many years later, after nerve axons came to be regarded as “core conductors.” In the core conductor concept, nerve axons are considered to be long, thin, cylindrical tubes of membrane filled with an electrically conducting axoplasm and immersed in a highly conductive

medium. Because the resistance across the membrane is much larger than the resistance through the axoplasm, over short distances along the cylinder, electric current will preferentially flow down the core. In fact current will flow through the core for a considerable distance before the total amount of current that has leaked out through the membrane becomes significant. This “core conductor” concept was given a mathematical framework in the 1870s when Weber derived and solved steady-state equations in cylindrical coordinates for three-dimensional current flow in and around an axon. Nevertheless, it was not until around 1900 that Hermann and others explicitly recognized that the reduction of these equations from three spatial dimensions to one spatial dimension (distance along the axon or cable) led to an equation equivalent to Lord Kelvin’s cable equation.

Quantitative comparison of cable equation calculations to experimental results requires the use of single fiber preparations, but such preparations were not available until the 1930s. Given the current emphasis on cable theory for dendritic neurons, it might seem surprising to many today to learn that the first applications of cable theory were to determine the passive electrotonic properties of axons. Axons are however the prototypical cable. Hodgkin and Rushton in their classic 1946 paper derived solutions of the cable equation for an infinite cable. They noted that weak sub-threshold currents produce a voltage change that varies linearly with current, and they applied their

cable equation solutions to recordings of such responses to estimate membrane capacity, membrane resistivity, and axoplasm and extracellular resistivity in lobster leg axons. Hodgkin and Rushton argued that an analysis of this “passive behavior is essential to any theory of excitation,” it “provides an insight into the structure of the surface membrane,” and “such an analysis must precede an understanding of the more complicated electrical changes which make up the nervous impulse itself.” Several investigators applied cable theory to estimate passive cable parameters in a number of giant invertebrate axons, and results have been summarized by Rall (1977; Table 1).

In the 1950s, the advent of glass micropipettes made it possible to stimulate and record intracellularly from neurons having diameters much smaller than those of the large invertebrate axons. Some of the early recordings were made from the soma of large motoneurons or pyramidal cells. It had been known from the time of Ramón y Cajal that these neurons possessed extensive dendritic trees, and in the late 1950s it was verified with the electron microscope that dendrites and dendritic spines were sites of synapses. What role did dendrites play in neuronal excitability, and how did dendritic properties affect integration of synaptic inputs? The early answers to these questions, based on interpretations of somatic recordings, turned out to be incorrect. It took the application of cable theory to these recordings by Rall (1957, 1959, 1960), along with subsequent work by Rall and others, to provide a correct understanding of the role dendrites play in signaling (for a detailed history, see commentaries and original papers in Segev et al. (1995)).

The application of cable theory to dendrites had to be different from the application to axons. First, while axons are long and can be effectively modeled as infinite cables, dendrites are much shorter, requiring solutions for a finite cable. Many such solutions are given by Rall (1959, 1960) and Jack et al. (1975). Second, axons tend to run for long distances without branching, but dendritic trees are highly branched. Solutions for branched dendrites are given in Rall (1959) and also Rall and Rinzel (1973) and Rinzel and Rall

(1974). Furthermore, Rall showed that under certain conditions a branched structure could be reduced to an “equivalent cylinder” allowing solutions for a finite cable to be applied to many cell types. Third, axons and dendrites play different roles in signaling, so the questions for cable theory to address are much different. For example, how far synapses are from the soma electrotonically is a fundamental question for dendritic neurons; simple electrotonic length formulas were derived by Rall (1969) to address this question, and much work in this area has been done by others since (for a review and references, see Rall and Agmon-Snir (1998)).

As information accumulates about voltage-dependent conductances in dendrites, one might question the relevance of passive cable theory to the study of dendritic neurons today. On this point, Rall and Agmon-Snir (1998) echo and extend the arguments for the importance of cable theory for axons given by Hodgkin and Rushton, quoted above, stating “the intuition and methods given by passive cable theory enhance our understanding of the integrative mechanisms even in excitable dendrites. The passive case is an important reference for the excitable case and helps us better understand the role of excitability. Moreover, the passive case is a useful approximation that, analyzed with powerful methods, gives rise to general rules concerning the role of the geometry of the dendritic tree and of passive biophysical properties.” Some of these general rules will be shown below.

The Cable Equation

Given that neurons can be represented as core conductors with a patch of membrane adequately approximated by an electric circuit (Fig. 1), the derivation of the cable equation is a straightforward application of Ohm’s law, Kirchhoff’s law, and the relationship $q = CV$. The most difficult part of the derivation is defining resistances, capacitances, and currents in the proper units and knowing how to convert these terms to specific resistances and capacitance. Given the circuit in Fig. 1, Ohm’s law leads to $\partial V_i / \partial x = -i_i r_a$ and $\partial V_e / \partial x = -i_e r_e$, Kirchhoff’s law provides $\partial i_i / \partial x = -i_m$ and $\partial i_e / \partial x = +i_m$, and $q = CV$ and Ohm’s law together give membrane current

Cable Equation, Fig. 1 Electric circuits for a membrane patch (a) and a neuron cable (b). r_m resistance of a unit length patch of membrane Ω cm, r_a axial resistance per unit length Ω /cm, c_m capacitance per unit length μ F/cm, i_m

membrane current per unit length mA/cm. Note membrane resistivity $R_m = r_m \pi d$ in Ω cm², membrane capacity $C_m = c_m / \pi d$ in μ F/cm², axial resistivity $R_a = r_a \pi d^2 / 4$ in Ω cm (also called R_i), and d diameter

$i_m = c_m \partial V_m / \partial t + (V_m - E_r) / r_m$. When these equations are combined, the result is the cable equation:

$$\frac{r_m}{r_a + r_e} \frac{\partial^2 V_m}{\partial x^2} = r_m c_m \frac{\partial V_m}{\partial t} + (V_m - E_r).$$

This equation can be rewritten as

$$\begin{aligned} \lambda^2 \frac{\partial^2 V}{\partial x^2} &= \tau \frac{\partial V}{\partial t} + V \quad \text{where } \lambda \\ &= \sqrt{\frac{r_m}{r_e + r_a}} \quad \text{and } \tau = r_m c_m \end{aligned}$$

with λ known as the space constant or length constant and τ known as the membrane time constant. In nondimensional form with $T = t/\tau$ and $X = x/\lambda$ this equation becomes

$$\frac{\partial V}{\partial T} = \frac{\partial^2 V}{\partial X^2} - V.$$

We usually neglect r_e (see Rall 1959) and express λ and τ in terms of specific resistances and capacitance as

$$\begin{aligned} \lambda &= \sqrt{\frac{R_m d}{4 R_a}} \quad \text{and } \tau \\ &= R_m C_m \quad \text{where } d \text{ is cable diameter.} \end{aligned}$$

Note that the above cable equation assumes current flow in one dimension, down the core of

the cable. This is a useful approximation because the length of axons and dendrites far exceeds the diameter making radial and angular flow of current negligible except in the immediate vicinity of a current source. A three-dimensional approach may be warranted when voltage changes in a large extracellular volume are of importance (Eisenberg and Johnson 1970), but in most cases, the one-dimensional cable equation is entirely appropriate.

Solutions for the Infinite Cable

For an axon, the assumption is that current is applied at a middle point $x = 0$, with the axon cable extending in both directions from this point to $\pm\infty$, with voltage being bounded. The solution obtained for these conditions by Hodgkin and Rushton (1946) and more directly by Jack et al. (1975) is

$$\begin{aligned} V(X, T) &= \frac{r_a I_0 \lambda}{4} \\ &\left\{ \exp(-X) \operatorname{erfc}\left(\frac{X}{2\sqrt{T}} - \sqrt{T}\right) - \exp(X) \operatorname{erfc}\left(\frac{X}{2\sqrt{T}} + \sqrt{T}\right) \right\} \end{aligned}$$

in nondimensional form, where I_0 is a constant current and erfc is the complementary error function. The solution above can be used to obtain two useful particular solutions – voltage at the stimulation site as a function of time, $V(0, T) = (r_a I_0 \lambda / 2) \operatorname{erfc}(\sqrt{T})$, and the steady-state voltage, $V(X, \infty) = (r_a I_0 \lambda / 2) \exp(-X)$. The former shows that voltage rises to 84% of its final value at $T = t/\tau = 1$ (compared to 63% for an

isopotential sphere), and the latter illustrates the usefulness of λ as a measure of voltage decay with distance.

Steady-State Solutions for Semi-infinite and Finite Cables

In the steady-state $\partial V/\partial t = 0$, reducing the cable equation to an ordinary differential equation,

$$\lambda^2 \frac{d^2 V}{dx^2} - V = 0.$$

This equation is easily solved, and the general solution can be expressed in various equivalent forms:

$$\begin{aligned} V(x) &= A_1 \exp(-x/\lambda) + A_2 \exp(x/\lambda) \\ V(x) &= B_1 \cosh(x/\lambda) + B_2 \sinh(x/\lambda) \\ V(x) &= C_1 \cosh((\ell - x)/\lambda) + C_2 \sinh((\ell - x)/\lambda) \end{aligned}$$

where ℓ is the length of the cable. The arbitrary constants depend on the boundary conditions (BC) which specify either the voltage or the current (derivative of the voltage) at the ends of the cable:

$$\begin{aligned} \text{Voltage BC : } V(0) &= V_0 \text{ and } V(\ell) \\ &= V_L \text{ or } V \text{ is bounded (not infinite).} \end{aligned}$$

$$\begin{aligned} \text{Current BC : } -\frac{1}{r_a} \frac{dV}{dx} \Big|_{x=0} &= i_i \text{ and } \frac{1}{r_a} \frac{dV}{dx} \Big|_{x=\ell} \\ &= i_e. \end{aligned}$$

Voltage boundary conditions are straightforward. The current boundary conditions come from Ohm's law and the convention that current is positive to the right, so one must be careful with the direction of the injected current, particularly at the end of the cable. This explains the lack of a minus sign for the current BC at $x = \ell$. Some commonly used current boundary conditions are:

$$\text{Sealed end : } -\frac{1}{r_a} \frac{dV}{dx} \Big|_{x=\ell} = 0.$$

$$\begin{aligned} \text{Leaky end : } -\frac{1}{r_a} \frac{dV}{dx} \Big|_{x=\ell} & \\ &= V(\ell) G_\ell \text{ e.g., } -\frac{1}{r_a} \frac{dV}{dx} \Big|_{x=\ell} \\ &= V(\ell) \left(\frac{\pi d^2}{R_m 4} \right) \text{ for an end cap.} \end{aligned}$$

$$\text{Current injection : } -\frac{1}{r_a} \frac{dV}{dx} \Big|_{x=0} = I_0.$$

Note that the leaky end condition would not have the minus sign if we considered leak at $x = 0$ because of the direction of the leak current. Simulation software packages typically assume a sealed end condition at terminations because the leak conductance, G_ℓ , through an end cap of membrane with the same membrane resistivity, R_m , as the dendrite turns out to be negligible.

Application of boundary conditions to the general solution leads to special solutions that provide significant insight. First, consider the semi-infinite cable where boundary conditions are $V(0) = V_0$ and $V(\infty)$ is bounded. These conditions lead to

$$V(x) = V_0 \exp\left(\frac{-x}{\lambda}\right).$$

For current input, I_0 , at $x = 0$, V_0 would be replaced by $r_a I_0 \lambda$ which is a factor of 2 larger than noted above for the infinite cable. This solution shows the significance of λ as a measure of voltage decay with distance in that voltage drops 1/e or 37% for each λ distance. It must be stressed that this result applies strictly only for semi-infinite and infinite cables – for finite cables with sealed ends, the decay is less.

As a second example, consider voltage clamp in a finite cable. Boundary conditions are $V(0) = V_0$ and sealed end at ℓ . The solution is

$$V(x) = V_0 \cosh\left(\frac{\ell - x}{\lambda}\right) / \cosh\left(\frac{\ell}{\lambda}\right).$$

One can use this expression to estimate how effective voltage clamp at the soma space clamps distal regions by considering the solution at $x = \ell$

or $V(\ell) = V_0/\cosh(\ell/\lambda)$. For cells with an electrotonic length $L = \ell/\lambda = 1$, the solution shows that the voltage change at the end of the cable is only 65% of the difference between V_0 and the resting potential. For transient inputs, the effective space clamp is considerably worse (Rall and Segev 1985).

A third useful case is the solution for current input in a finite cable. Boundary conditions are current input at $x = 0$ and sealed end at $x = \ell$. The solution is

$$V(x) = \frac{r_a \lambda I_0 \cosh((\ell - x)/\lambda)}{\sinh(\ell/\lambda)}.$$

This solution is useful for illustrating the dependence of input resistance, R_N , a measure of cell excitability, on various electrotonic and morphological factors:

$$\begin{aligned} V(0) &= \frac{r_a \lambda I_0}{\tanh(\ell/\lambda)} \text{ so } R_N = \frac{r_a \lambda}{\tanh(\ell/\lambda)} \\ &= \left(\frac{2}{\pi}\right) \frac{\sqrt{R_m R_a} d^{-3/2}}{\tanh(\ell/\lambda)}. \end{aligned}$$

The last expression shows the dependence of input resistance on $d^{3/2}$, a factor that proves to be important for branched case solutions and reduction of a branched tree to an equivalent cylinder. Note that as $\ell \rightarrow \infty$, $R_N \rightarrow r_a \lambda$ in agreement with the semi-infinite solution above. Alternatively, we say that the input conductance of a semi-infinite cylinder, $G_\infty = 1/(r_a \lambda)$. It is straightforward to convert the last expression above into the following useful equations:

$$R_N = \frac{R_m L}{A_D \tanh(L)} \quad \text{also} \quad R_m = \frac{R_N A_D \tanh(L)}{L}$$

where $L = \ell/\lambda$ is electrotonic length and A_D is the membrane area of the cable. The first of these expressions shows the dependence of input resistance on membrane area, electrotonic length, and membrane resistivity, and the second is useful for estimating R_m when input resistance, membrane area, and electrotonic length are known or alternatively for estimating membrane area when input resistance, membrane resistivity, and electrotonic

length are known. A means to estimate electrotonic length independently is described below.

Another useful case is current input at $x = 0$ and leaky end at $x = \ell$. In this case, the solution is

$$V(x) = \frac{r_a \lambda I_0 [\cosh((\ell - x)/\lambda) + (G_L/G_\infty) \sinh((\ell - x)/\lambda)]}{\sinh(\ell/\lambda) + (G_L/G_\infty) \cosh(\ell/\lambda)}$$

where G_L is the leaky end conductance and G_∞ is the conductance of an infinite extension of the cable (semi-infinite cylinder) as defined above. If $G_L = 0$ (sealed end), we get the solution shown earlier for current input into a finite cylinder. If $G_L = G_\infty$, then the leak is equivalent to an infinite extension of the cylinder and $V(x) = I_0/G_\infty \exp(-x/\lambda)$ as shown above for the semi-infinite cylinder. If $G_L = \infty$, then the solution represents the case where voltage at the end is clamped to 0. It is interesting to think about what other values of G_L/G_∞ might mean. A value of $G_L/G_\infty = 2$ might correspond to the attachment of an infinite extension of not one but two cylinders or perhaps flare in dendritic tree diameters; conversely, $G_L/G_\infty = 0.5$ might represent taper. Sample solutions for a number of different boundary conditions are shown in Fig. 2.

Steady-State Solutions for Branched Dendritic Trees

Steady-state solutions for branched dendritic trees can be obtained by letting each dendritic segment be represented by a finite cable and then connecting these cable segments at the branch points using continuity of voltage and conservation of current. It is useful to express the resulting equations in terms of the unknown voltages at the nodes – branch points, terminations, and the start. For a dendritic tree with n segments, the solution would require solving $n + 1$ simultaneous equations for voltages at the nodes. From these voltages, it is then possible to compute the voltage anywhere in the dendritic tree.

Another approach is to use the iterative algorithm proposed by Rall in 1959. In this algorithm, additional cylinders at branch points are considered as a leak conductance at the end of the parent cylinder and use is made of the leaky end solution of the cable equation given just above. The leak

Cable Equation,

Fig. 2 Voltage attenuation with distance. *a*, Infinite cylinder; *b*, *c*, *d*, voltage clamp to rest in cylinders with $L = 2$, 1, and 0.5; *e*, *f*, *g*, sealed end in cylinders with $L = 2$, 1, and 0.5. (From Rall (1959), Fig. 3 with permission from Elsevier)

conductance of the initial cylinder equals the sum of the input conductances of attached cylinders, which each have a leak conductance equal to the sum of the input conductances of their attached cylinders, and so forth iteratively, until terminations are reached. The leak conductance at terminations is assumed to be known, typically zero or sealed end. Given the leak conductance at terminations, the input conductance of the terminating branches can be computed, and the sum of input conductances of terminating branches having the same parent becomes the leak conductance of the parent branches, which allows the input conductance of the parent branches to be computed, iteratively, back to the initial segment. With input conductance of the initial cylinder known, along with the leak conductances G_L and G_∞ for all three segments, the voltage can then be computed iteratively from the starting segment out to terminating segments. Numerical examples of this procedure are given in Rall (1959) and Jack et al. (1975).

Although the above approaches, along with compartmental modeling approaches, can be used to obtain steady-state solutions for cells with arbitrarily branched geometry, these solutions do not provide the understanding and insight that can be obtained with closed form mathematical solutions. Rall and Rinzel (1973) constructed an idealized branched neuron model

with suitable symmetry assumptions and equivalent cylinder constraints on branch diameters and were able to apply superposition to obtain mathematical solutions for the case when input was applied to only one distal branch of the dendritic tree. Explicit expressions were given for input resistance at the site of input and for voltage attenuation from the input location to the soma. Numerical illustrations showed how branch input resistance and voltage attenuation, factors important for the effectiveness of synaptic inputs, depend on certain morphological and electrotonic properties of the dendritic tree. A result of particular note is the asymmetric attenuation toward the soma compared with attenuation toward the periphery as shown in Fig. 3.

Transient Solutions to the Cable Equation

Transient solutions to the cable equation have been derived for various conditions. Mentioned above is the solution by Hodgkin and Rushton for the infinite cable, computed via Laplace transforms. A number of investigators have developed solutions with the use of Laplace transforms for various boundary conditions including Rall (1960), Jack and Redman (1971a, b), and others. The analysis from Rall (1960) was particularly important for showing that estimates of the membrane time constant from recordings of voltage

Cable Equation, Fig. 3 Asymmetric voltage attenuation. Steady-state voltage attenuation with input at location I (solid line) or with the same input at the soma (dotted line). Note the steep attenuation from I to the soma and the lack of much attenuation from any branch point toward the periphery. Note also that the soma voltage for input at I equals the voltage at I for input at the soma. This illustrates the reciprocity property of linear systems. (Figure reproduced from *The Book of Genesis* ©2003 James M Bower and David Beeman which was based on Fig. 4 from Rall and Rinzel (1973) reproduced with permission from Elsevier)

transients were much too small when dendritic trees were not considered appropriately. Other methods of solution make use of Green's functions.

Transient solutions for branched dendrites can become very complicated and not very insightful without some simplifying assumptions, as evidenced by solutions with the Laplace transform approach by several investigators. However, the development by Rall (1962) of the equivalent cylinder model allowed the analysis to be simplified significantly (see entry ► “Equivalent Cylinder Model (Rall)”). Briefly, Rall showed that with a certain set of assumptions, a highly branched dendritic tree could be reduced mathematically to a single equivalent cylinder. Solutions that make use of the equivalent cylinder assumption to

provide particularly insightful results have been obtained by Rall (1969) and Rinzel and Rall (1974) as we will now discuss.

Rall (1969) assumed that a neuron's dendritic tree could be approximated by an equivalent cylinder and used separation of variables to solve the cable equation, obtaining in nondimensional form:

$$V(X, T) = (A \sin(aX) + B \cos(aX)) \exp[-(1 + \alpha^2)T].$$

Boundary conditions and the initial condition are then used to evaluate the constants A, B, and α . Applying sealed end boundary conditions at both ends gives

$$V(X, T) = \sum_{n=0}^{\infty} B_n \cos\left(\frac{n\pi X}{L}\right) \exp\left[-\left(1 + \left(\frac{n\pi}{L}\right)^2\right)T\right]$$

where then B_n have to be obtained from the initial condition, $V(X, 0)$. Regardless of the initial condition, the exponential term in the above equation shows that the voltage will decay back to rest with an infinite number of time constants defined by

$$\frac{1}{\tau_n} = \left[\frac{1 + (n\pi/L)^2}{\tau_0} \right] \text{ or } \tau_n = \frac{\tau_0}{1 + (n\pi/L)^2}$$

where we have replaced T by t/τ and then include the factor $1 + (n\pi/L)^2$ to define the τ_n . Note that $\tau_0 = \tau_m$, the membrane time constant, when membrane properties are uniform. Then we can simplify our solution to:

$$V(X, t) = \sum_{n=0}^{\infty} C_n \exp(-t/\tau_n).$$

Rall called the τ_n “equalizing time constants.” In a cylinder, the initial voltage decay is fast, as it is governed by the fast time constants which describe how voltage “equalizes” among the dendrites, while the final slower decay is governed by the membrane time constant. A sphere or uniformly polarized cell has only one decay time constant, the slow membrane time constant. It was ignoring the fast time constants and trying to fit voltage transients with just one exponential

term that led to the significant underestimation of the membrane time constant by some investigators in the 1950s and early 1960s. Note that voltage charging is also faster in a cylinder than in a sphere. This may seem counterintuitive if the fast time constants are “equalizing time constants.” To explain this paradox, it must be remembered that in a sphere, the capacitance of the whole cell has to be discharged before significant current flows through the membrane, whereas in a cylinder, only local capacitance has to be discharged before there is local membrane current flow; consequently, voltage charging begins earlier.

The usefulness of this transient solution was pointed out by Rall who showed that if τ_0 and τ_1 could be estimated from an experimental transient, then the electrotonic length of the dendritic tree $L = \ell/\lambda$ can be estimated with the following formula:

$$L = \frac{\pi}{\sqrt{\tau_0/\tau_1 - 1}}.$$

In early studies, the time constants were estimated by a procedure called “exponential peeling,” but with the advent of sophisticated computers and software, nonlinear curve fitting methods are used. Estimates of L tell us if the cell is electrotonically compact or not. This is important for estimating the effectiveness of synaptic inputs and in particular the strength of distal inputs compared to identical proximal inputs and also for estimating the extent of space clamp during voltage clamp. There are a number of other formulas that can be used to estimate L , although the one given above is considered to be the most robust. A caveat is that L estimates made with this formula assume that the cell can be approximated as an equivalent cylinder; deviations from this assumption will influence τ_1 and will cause errors in the L estimate (see entry ► “[Electrotonic Length, Formulas and Estimates](#)”).

Rinzel and Rall (1974) developed a transient solution for a branched dendritic tree using the same idealized dendritic tree and similar symmetry assumptions and superposition methods as used in their steady-state solutions for a branched tree mentioned above. The mathematical

expressions derived were used to illustrate the attenuation and delay characteristics of the voltage peak caused by a transient input in a distal branch as it proceeds to the soma. While voltage attenuation of transient inputs from the input site to the soma was considerably more severe than that observed previously for steady-state inputs, a significant fraction (about half) of the input charge (the integral of the voltage change) was nonetheless delivered to the soma. Expressed another way, the attenuation of the integral of the voltage between the input site and the soma equals the steady-state attenuation between these two locations. These calculations also showed that the time to peak and half-width of the voltage response at the soma depend on the distance of the input from the soma. Some of these results are illustrated in Fig. 4.

Insights from Cable Equation Solutions

Cable equation solutions have provided considerable insight leading to a quantitative and qualitative understanding of how neurons function. Insights may have come from solutions for simplified neuron structures with particular assumptions about branching and diameters at branch points and passive membrane with (usually) uniform properties, but their applicability is general. The list below is long but is not meant to be exhaustive:

1. *Space constant* λ . The space constant (length constant) λ is a useful qualitative measure of voltage decay with distance along a cable. However, as a quantitative measure, λ is the distance over which the steady-state voltage decays to $1/e$ or 37% of its value at the origin *only* in infinite and semi-infinite cables. Electrotonic length and boundary conditions, as well as the presence of side branches, matter for steady-state voltage attenuation in finite cables.
2. *Membrane time constant* τ . The membrane time constant τ is a useful qualitative measure of how voltage decays in time. However, as a quantitative measure, τ is the time it takes for voltage to decay to $1/e$ or 37% of its initial value *only* in an isopotential or uniformly

Cable Equation, Fig. 4 Voltage attenuation for transient inputs. Input is at BI. *Left*: voltage attenuation to the branch points. *Right*: voltage attenuation to the terminals. Note how much less attenuation is from the branch points to the

terminals than between branch points. Compare with Fig. 3. (Reproduced from Rinzel and Rall (1974) Figs. 4 and 5 with permission from Elsevier)

polarized cell. Additional time constants affect the early voltage time course depending on morphology. Neglect of these additional time constants can lead to erroneous estimates of τ in dendritic neurons.

3. *Summation of inputs.* In a linear system, the solution for two current inputs is the sum of the solutions for each input. This is helpful for understanding spatial and temporal summation of synaptic inputs if they are small. However, it should be noted that synaptic inputs, being a conductance multiplied by a driving force, are not linear, so results should be interpreted with caution.
4. *Reciprocity.* In a linear system, the voltage response at the soma to current injection at a dendritic location will equal the voltage response at this dendritic location following the same current injection at the soma. This result applies generally for any two points in the cell and can be used to determine if a dendritic tree is passive or if blockers have made it so.
5. *Input resistance calculations.* Cable theory solutions can be used to calculate the input resistance in any passive branched dendritic tree. Input resistance can be much higher in distal dendrites than at the soma. The smaller diameter of the dendritic branch produces a larger voltage response to current injection. Boundary conditions also play a role.

6. *Steady-state voltage attenuation depends on cylinder electrotonic length and boundary conditions.* As mentioned above, steady-state voltage attenuation is described quantitatively by λ only for infinite and semi-infinite cables. For finite cylinders, both cylinder electrotonic length and boundary conditions affect attenuation. If the terminal boundary condition is a sealed end, attenuation with distance is less in electrotonically shorter cylinders than longer ones. If the terminal boundary condition is voltage clamp to rest, attenuation with distance is larger in electrotonically shorter cylinders than longer ones. The sealed end and voltage clamp to rest conditions represent two extremes that determine voltage attenuation (Fig. 2).
7. *Voltage attenuation is asymmetric.* A segment of dendrite within a dendritic tree will have a certain core resistance, but voltage attenuation across this core resistance will be asymmetric, depending on the boundary conditions at the ends of the segment. For an input in a distal branch, the boundary condition heading proximally toward the soma is a very leaky end, approaching a voltage clamp to rest condition, while the boundary condition heading distally is a not very leaky end, approaching a sealed end condition. Consequently, applying the previous point above, there will be severe attenuation heading

proximally, but little attenuation heading distally. This explains the asymmetric attenuation in Fig. 3. The degree of voltage attenuation across a segment depends on how much the terminal boundary condition in the direction current is flowing that resembles a “sealed end” or “clamp to rest” condition.

8. *Transient voltage attenuation is more severe.* Voltage attenuation is more severe for transient inputs than for steady-state inputs. Nevertheless, the attenuation of the integral of the voltage change over time, with the integral computed at the input site and at the soma, equals the steady-state voltage attenuation between these two locations.
9. *Dendritic filtering.* In passive systems, dendrites provide low-pass filtering of the voltage response to synaptic inputs. As the signal travels to the soma, the voltage response is attenuated and becomes spread out. A shape index which plots EPSP half-width vs. time to peak can be used to predict the electrotonic location of the synapse. Note however that the shape index will depend not only on the synaptic location but also on the time course of the synaptic conductance and the electrotonic length of the dendritic tree as well.
10. *The $d^{3/2}$ and signal attenuation.* If dendrite diameters at branch points satisfy the “3/2 rule,” $d_p^{3/2} = d_{d1}^{3/2} + d_{d2}^{3/2}$, where d_p is the diameter of the parent branch and d_{d1} and d_{d2} are diameters of daughter branches, then there is impedance matching at branch points, and the attenuation with electrotonic distance remains unchanged. However, if diameters at branch points do not satisfy this condition, attenuation will be steeper or less steep after the branch point depending on whether the exponent is less than 3/2 or greater than 3/2, respectively. Changes in the summed $d^{3/2}$ along dendrites control signal attenuation.
11. *Consequences for voltage clamp.* Attenuation out from soma is relatively small. Recall that the analytic solution for voltage at the end of a cylinder given voltage clamp at the origin is $V(L) = V(0)/\cosh(L)$. This equation allows us to estimate the extent of space clamp in the cell when the soma is voltage clamped. Although much of the voltage change at the soma is felt at the distal dendrites, the space clamp is far from perfect at distal locations, and this can be very important in interpreting results.
12. *Implications for placement of excitatory and inhibitory inputs.* The differences in input resistance at the soma and distal dendrites, the asymmetry of voltage attenuation, and the solution for voltage clamp at the soma have implications for the placement of excitatory and inhibitory inputs. Regarding inhibition, inhibition is most effective when placed at the soma because the effect is felt throughout the cell. Regarding excitation, soma input will not produce the large changes in voltage seen with more distal input, so excitation at the soma is less likely to activate voltage-gated conductances, suggesting that excitation might be better placed in the dendrites. If there are voltage-gated conductances in the dendrites, the large distal voltage changes could activate them and amplify the signal.
13. *Electrotonic length.* The electrotonic length, L , of the dendritic tree can be estimated from experimental measurements of τ_0 and τ_1 if the cell can be approximated as an equivalent cylinder. However, one must be careful in the interpretation of the time constants when the cell deviates from an equivalent cylinder. Most neurons have an electrotonic length of 1 or less.
14. *Dendritic spines.* Dendritic spines represent a special case of asymmetric voltage attenuation. Voltage attenuation will be steep from the spine head to the dendrite because the boundary condition at the spine-dendrite junction resembles a very leaky end. However, there will be negligible voltage attenuation from the dendrite to the spine head because the boundary condition at the tip of the spine head is practically a sealed end.
15. *Effect of reconstruction errors.* Cable theory can explain effects of reconstruction errors on parameter value estimates. Dendrite

diameters are notoriously difficult to measure accurately because diameters are near the optical resolution of the microscope. Length values can be inaccurate because of tissue shrinkage, particularly in the z-axis. Cable theory says if the reconstruction diameters are uniformly off by a factor of x , then the R_m , C_m , and R_a values used in models should be equal to the actual R_m multiplied by x , the actual C_m divided by x , and the actual R_a multiplied by x^2 . If reconstruction lengths are uniformly off by a factor y , then the R_m , C_m , and R_a values used in models should be equal to the actual R_m multiplied by y , the actual C_m divided by y , and the actual R_a divided by y .

16. *Optimal diameters.* Cable theory calculations suggest that a neuron can optimize the effectiveness of distal inputs with its morphology or electrotonic parameters. For a cylinder of given length, if diameter is small, input resistance is large, and attenuation is steep, whereas if diameter is large, input resistance is small, and there is much less attenuation. Because of this trade-off between input resistance and attenuation, there will be a diameter that will maximize the effectiveness inputs delivered at the end of the cable.
17. *Modeling cells as an equivalent cylinder.* To a first approximation, dendrites can be modeled as an equivalent cylinder. This approximation is useful for providing insights into how voltage changes in dendritic trees.

Calcium Buffering: Models of

Hartmut Schmidt

Carl-Ludwig-Institute for Physiology, Leipzig,
Germany

Definitions

Neuronal Ca^{2+} dynamics are tightly controlled by endogenous calcium-binding proteins (CaBPs), which may bind one or more Ca^{2+} ions either in a cooperative or noncooperative manner. The binding of Ca^{2+} to buffers can be described kinetically by using binding and unbinding rate constants in ordinary differential equations (ODEs) or by using equilibrium constants. In addition to buffering, some CaBPs perform specific Ca^{2+} -dependent actions on downstream targets; these are termed Ca^{2+} sensors and are modeled similarly, except that target reactions are included. Finally, perturbations by Ca^{2+} indicator dyes, which are themselves buffers, can be addressed similarly.

Detailed Description

Background

Opening of Ca^{2+} permeable channels results in steep increases in the intracellular free Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$) that can reach tens of micromol/liter at the entry site. Ca^{2+} buffers make a major contribution to reducing $[\text{Ca}^{2+}]_i$ to lower levels within milliseconds and to limiting the spatial extent of $[\text{Ca}^{2+}]_i$. Thus, buffering is central for maintaining a high temporal responsiveness to $[\text{Ca}^{2+}]_i$ signals, which is eminent for neuronal coding.

Second-Order Buffer Reaction

Chemical Reaction

The simplest reaction is binding of Ca^{2+} to a buffer (B) with only one binding site:

$$[\text{B}]_f = [\text{B}]_T - [\text{CaB}] \quad (2)$$

$$K_D = \frac{1}{K_A} = \frac{k_{\text{off}}}{k_{\text{on}}} = \frac{[\text{B}]_f [\text{Ca}]_i}{[\text{CaB}]} \quad (3)$$

$[\text{Ca}^{2+}]_i$, $[\text{B}]_f$, and $[\text{CaB}]$ are the concentrations of free Ca^{2+} , free buffer, and Ca^{2+} buffer complex, respectively. $[\text{B}]_T$ is the total buffer concentration. K_D and K_A are the equilibrium dissociation and association rate constants, respectively. In neuronal modeling, it is convenient to use K_D . Note that a higher K_D value implies that the buffer has a lower affinity for Ca^{2+} and is less easily saturated. Concentrations and K_D are in units of M (mol/liter). k_{on} (unit: $\text{M}^{-1} \text{s}^{-1}$) and k_{off} (s^{-1}) are the forward and backward binding rate constants, respectively, determining the velocity of the reaction.

Kinetic Model

The above reactions together with a Ca^{2+} influx can be converted to ODEs for each well-mixed compartment, assuming mass action kinetics (Markram et al. 1998; Schmidt et al. 2003):

$$\frac{d[\text{Ca}]_i(t)}{dt} = J + R \quad (4)$$

$$\frac{d[\text{B}]_f(t)}{dt} = R \quad (5)$$

$$\frac{d[\text{CaB}](t)}{dt} = -R \quad (6)$$

$$R = -k_{\text{on}}[\text{Ca}]_i(t) [\text{B}]_f(t) + k_{\text{off}}[\text{CaB}](t) \quad (7)$$

where R is the reaction term and J the Ca^{2+} influx, both in units of M/s. In order to solve the system numerically (► [Deterministic Reaction-Diffusion Simulators](#)), starting conditions for $t = 0$ are determined by assigning $[\text{Ca}^{2+}]_i(0) = [\text{Ca}^{2+}]_{\text{rest}}$ and by calculating $[\text{B}]_f(0)$ and $[\text{CaB}](0)$ from Eq. 3.

From a brief increase, $[\text{Ca}^{2+}]_i$ relaxes approximately exponentially to a value determined by K_D , and the fraction of Ca^{2+} bound buffer

Calcium Buffering: Models of, Fig. 1 $[Ca^{2+}]_i$ decay kinetics (a) and fractions of Ca^{2+} -bound buffers (b) after a 100 μM influx step in the presence of either a rapid (solid lines, $k_{on} = 10^8 M^{-1} s^{-1}$, $k_{off} = 100 s^{-1}$) or a slow (dashed lines $k_{on} = 10^7 M^{-1} s^{-1}$, $k_{off} = 10 s^{-1}$) buffer, both with a K_D of 1 μM and $[B]_T$ of 100 μM . Dotted lines indicate resting levels

increases concomitantly (Fig. 1). The time constant is determined by k_{on} , k_{off} , $[Ca^{2+}]_i$, and $[B]_f$ but can be approximated as $\tau \approx 1/(k_{on} [B]_f(\infty))$ (Markram et al. 1998).

Rapid Buffer Approximation (RBA)

The RBA is a steady-state simplification for binding in well-mixed compartments under the assumption of quasi-instantaneous equilibration of all reactants (Neher 1998). Although this assumption is not met during rapid signaling, the RBA is often useful. Combining Eqs. 2 and 3 ($[B]_f$ is typically unknown, whereas $[B]_T$ may be estimated experimentally) and rearranging yields.

$$[CaB] = \frac{[B]_T [Ca]_i}{K_D + [Ca]_i} \quad (8)$$

Using Eq. 8, the total Ca^{2+} concentration (free and bound Ca^{2+}) is given by

$$\begin{aligned} [Ca^{2+}]_T &= [Ca^{2+}]_i + [CaB] \\ &= [Ca^{2+}]_i + \frac{[B]_T [Ca]_i}{K_D + [Ca]_i} \end{aligned} \quad (9)$$

By differentiating $[CaB]$ with respect to $[Ca^{2+}]_i$ in Eq. 8, the “buffer capacity” (κ) is defined, which gives a dimensionless measure of how many Ca^{2+} ions are bound for each free Ca^{2+} . For example, κ of 100 (a typical value for neurons) implies that 100 Ca^{2+} are bound for each free Ca^{2+} :

$$\kappa = \frac{d[CaB]}{d[Ca]_i} = \frac{K_D [B]_T}{(K_D + [Ca]_i)^2} \quad (10)$$

By differentiating $[Ca^{2+}]_T$ with respect to $[Ca^{2+}]_i$ in Eq. 9 and inverting the result, the “buffering factor” (β) is defined, which is a number between zero and one and a measure of the fraction of Ca^{2+} remaining free:

$$\beta = \frac{d[Ca]_i}{d[Ca]_T} = \frac{1}{1 + \kappa} \quad (11)$$

The usefulness of κ and β becomes apparent when considering the sum of Eqs. 4 and 6 for the total Ca^{2+}

$$\frac{d[Ca]_T(t)}{dt} = J \quad (12)$$

and then deriving the change in $[Ca^{2+}]_i$

$$\frac{d[Ca]_i(t)}{dt} = \frac{d[Ca]_i(t)}{d[Ca]_T(t)} \frac{d[Ca]_T(t)}{dt} = \beta J \quad (13)$$

Equation 13 quantifies the degree to which a very rapid buffer limits the impact of a Ca^{2+} influx J on $[Ca^{2+}]_i$ in a well-mixed compartment. Although κ and β are functions of Ca^{2+} , they can be regarded as constant if $[Ca^{2+}]_i \ll K_D$. On the other hand, if $[Ca^{2+}]_i \gg K_D$, then $\kappa \rightarrow 0$ and $\beta \rightarrow 1$, i.e., the buffer is saturated.

Competition Between Rapid and Slow Buffers

A neuron typically expresses multiple CaBPs (with different kinetics) that compete for Ca^{2+}

Calcium Buffering: Models of, Fig. 2 Competition of fast and slow buffer for Ca^{2+} . (a) $[\text{Ca}^{2+}]_i$ kinetics as in Fig. 1 but in the presence of both buffers. (b) Ca^{2+} bound fractions of the rapid (solid line) and the slow buffer (dashed line) as in Fig. 1 but now during competition. Note the difference in their binding behavior compared to Fig. 1

binding. In such a system, the amount of Ca^{2+} bound to a given buffer can initially deviate substantially from the equilibrium (Markram et al. 1998). A rapid buffer will initially bind more Ca^{2+} than predicted from equilibrium, while the slow buffer will bind less Ca^{2+} . Later on, Ca^{2+} liberated by the rapid buffer will be bound by the slow buffer, and both will relax to their equilibrium occupancy (Fig. 2). This generates multiphase $[\text{Ca}^{2+}]_i$ decay kinetics (Schmidt et al. 2003).

Competition Between Ca^{2+} and Mg^{2+}

CaBPs bind other divalent cations like Mg^{2+} . The competition is included by adding ODEs for Mg^{2+} similar to those for Ca^{2+} . This shifts the effective K_D for Ca^{2+} towards larger values (Fig. 3, Schmidt 2012).

Higher-Order Buffering

Many CaBPs have several binding sites that may cooperate with each other, i.e., binding of Ca^{2+} to one site facilitates (positive cooperativity) or

hinders (negative cooperativity) binding of Ca^{2+} to other sites. This is expressed by different k_{on} and k_{off} for the individual steps. In a two-step reaction, for example, positive cooperativity means that $k_{\text{on},2} > k_{\text{on},1}$ and/or $k_{\text{off},2} < k_{\text{off},1}$, such that $K_{D,2} < K_{D,1}$. Calretinin is an example for positive cooperativity (Faas et al. 2007):

The corresponding reaction rate is

Replacing R by R_c in Eqs. 4, 5, and 6 yields the ODEs for the kinetic simulation.

Spatial Resolution

Spatial resolution can be achieved by subdividing a well-mixed compartment into smaller compartments that are coupled by diffusion. This is obtained by introducing diffusion flux terms J_D (M/s) into Eqs. 4, 5, and 6 for each compartment n (Markram et al. 1998; Schmidt et al. 2013):

$$J_D = D_x \frac{A_{n,n+1}}{dV_n} ([X]_{n+1}(t) - [X]_n(t)) \quad (16)$$

where D_x (m^2/s) is the diffusion coefficient of species X, A the exchange surface area, d the distance between subcompartments, and V their volume.

Spatial resolution can also be obtained by converting Eqs. 4, 5, 6, and 7 to partial differential equations (PDEs) with the spatial coordinates as

Calcium Buffering: Models of, Fig. 3 Steady-state Ca^{2+} -binding curves for parvalbumin ($K_{D,\text{Ca}} = 9 \text{ nM}$, $K_{D,\text{Mg}} = 31 \text{ } \mu\text{M}$) in the absence (dotted line) and presence (solid line) of $600 \text{ } \mu\text{M}$ $[\text{Mg}^{2+}]_i$

additional independent variables. The independent variables are omitted in the following for clarity:

$$\frac{\partial [\text{Ca}]_i}{\partial t} = D_{\text{Ca}} \nabla^2 [\text{Ca}]_i + R + J \quad (17)$$

$$\frac{\partial [\text{B}]_f}{\partial t} = D_{\text{B}} \nabla^2 [\text{B}]_f + R \quad (18)$$

$$\frac{\partial [\text{CaB}]}{\partial t} = D_{\text{CaB}} \nabla^2 [\text{CaB}] - R \quad (19)$$

The system can be solved numerically by the method of finite elements, i.e., by breaking down the total geometry into a finite number of sub-compartments (meshing).

Limitations

Real chemical reactions are discrete events that depend on the collision of the reactants, i.e., they are stochastic and noisy. With larger numbers of molecules, the reactions are well described by the deterministic differential equations. For small molecule numbers, the effects of noise may become important, and it could be appropriate to use stochastic simulation. Such a Monte Carlo

simulation is more time-consuming, and it has to be carefully weighted whether it is really required. As a rule of thumb, a reaction with less than 100 molecules is likely to be more adequately described stochastically (Bhalla and Wils 2009).

Definition

Calcium is a key but a ubiquitous messenger in cell physiology. Yet direct electrophysiological or light imaging measurements are limited by the intrinsic small nano- to micrometer space where chemical reactions occur and also by the small number of molecules. Thus any fluorescence dye molecule added to measure the number of calcium ions can severely perturb the endogenous chemical reactions. Over the years, an alternative approach based on modeling, mathematical analysis, and numerical simulations has demonstrated that it can be used to obtain precise quantitative results about the order of magnitude, rate constants, the role of the cell geometry, and flux regulation across scales from channels to the cell level.

The aim of this ECN is to present physical models of calcium ions from the molecular description to the concentration level and to present the mathematical tools used to analyze the model equations. From such analysis, asymptotic formulas can be obtained, which are usually valid

for a certain range of parameters. However these formulas allow exploring at low cost the parameter space. The methods to analyze these equations are part of the classical analysis of partial differential equations and stochastic processes, which will not be reviewed here (see Schuss 1980, 2010a). We shall present several models related to diffusion, where formulas can be derived, and we shall specify how these formulas are used to extract parameters from experimental measurements. But in general models are far too complicated to lead to equations that can be analyzed, and most of the time, numerical simulations have to be built. Building rational simulations requires discretizing the physical equations and bridging the gap between the limits of the equations and the physical description that they account for. We will present here several stochastic simulations and their rules, limitations, and tricks that have been developed over the years. As we shall see here, any bottleneck in the equation can lead to heavy simulations running for days. In that case, coarse graining is a key step to reduce the complexity of the equation so that some analysis can be obtained and can be used to check in some limit the validity of the simulations.

All together physical modeling, mathematical analysis, numerical simulation, and their application to the statistical analysis of experimental data form an ensemble of approaches that are used today to better understand molecular interaction in nano- to microdomains. But the most striking convergence of these methods is to derive physiological laws from their first physical principles. We shall present (1) stochastic modeling of calcium ions and their trajectories, (2) modeling of local interactions with discussion of the rate constants, (3) derivation of asymptotic formulas for the residence of calcium in microdomains and dendritic spines, (4) modeling and simulation of diffusion in a crowded three-dimensional dendrite, (5) modeling of calcium in the spines, (6) modeling the CaM activation pathway, and (7) modeling of coarse-grained Markov chain to estimate the probability that the number of calcium ions bound to key molecule is reached. Finally, we shall discuss how these simulations can be used to study physiological processes

such as transient calcium ions in a dendritic spine, long-term potentiation induction, or what limits the spread of calcium following synaptic stimulations.

Detailed Description

Neuronal Microdomains

Neurons can be decomposed into several key microdomains involved in specific functions: dendrites integrate electrical signals, whereas dendritic spines are microcompartments receiving the postsynaptic terminal of excitatory synapses (Fig. 1). The presynaptic terminal is also a key compartment that controls calcium in relation to vesicular release. Dendrites further decompose into distal and apical dendrites which seem to have different electrophysiological properties that can be correlated with a difference in the structure. The soma and the axon are also separate compartments. We show in Fig. 1 different distinct compartments. Finally, it was found that aspiny neurons can confine calcium for a time scale comparable to a dendritic spine (Goldberg et al. 2003). Can organelles such as vesicles or endoplasmic reticulum control calcium concentration?

Diffusion in Neuronal Microdomains: Stochastic Modeling

We start with a Brownian description of calcium ions. Indeed motion due to thermal fluctuations is the main driving force for the motion of particles such as ions or molecules. Calcium motion has been well approximated as diffusion, which confirms that the ionic charge is screened. This is not the case for calcium influx through channels, where the nanometer space restriction is a dominant factor for the interaction between the channel charges and the ion (Benazzila 2000; Eisenberg et al. 1995). In cells, long distances are overcome mostly by the diffusion process. For example, free calcium ions diffuse in the dendritic spines or any neuronal microdomain in the dendrite or the axons (Korkotian et al. 2004). At the molecular level, diffusion of ions is described by a random walk. When an ion meets any plasma membrane, it is reflected or translocated inside an organelle at

pumps or exchangers. The transition from one region to another can be modeled by specifying absorbing conditions in specific boundary regions, such as the fictive separation between a dendrite and a spine.

Description of Calcium Stochastic Trajectories

A calcium ion trajectory is described by the Smoluchowski limit in the large damping approximation of the Langevin equation. The position x at time t satisfies the stochastic equation

$$\gamma[\dot{x} - V(x, t)] + F(x) = \sqrt{2\varepsilon\gamma}w. \quad (1)$$

Here $\varepsilon = k_B T/m$, where T is the temperature and k_B the Boltzmann constant; $\gamma = 6\pi a\eta$ is the dynamical viscosity, where η is the viscosity coefficient per unit mass and a is the radius of the ion. w is a random white noise modeling the thermal fluctuations, and the electrostatic force is

$$F(x) = -ze\nabla_x U_0(x),$$

where U_0 is the potential created by the site where the proteins are located. In a first approximation, each protein creates a localized parabolic potential, where the depth can be calibrated by using the backward-binding rate and the radius by using the forward-binding rate (Korkotian and Segal 2006). The frictional drag force, $-\gamma[\dot{x} - V(x, t)]$, is proportional to the relative velocity of the ion and the cytoplasmic fluid. The field of fluid $V(x, t)$ induced by calcium ions will be discussed below.

The Langevin Equations

We shall here explain the physical consideration behind the reduction to Eq. 1. For a dendritic spine containing N ions of different species (e.g., Ca^{++} , Na^+ , Cl^- , and so on), $\mathbf{x}_i(t)$ is the displacement vector of the i -th ion, m_i is its mass, and z_i is its valence. $\tilde{\mathbf{x}} = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N)$ is the coordinate of the N ions in configuration space. We consider a given flow field $V(\mathbf{x}, t)$ (see description below) and that ions interact with a fixed potential of the charges on the proteins, $U_0(\mathbf{x})$, and with the variable potential of all other ions. The variable potential consists of both the electrostatic ion-ion interaction potential, $U_{ii}(\tilde{\mathbf{x}})$, and the potential of

Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis, Fig. 1 Neuronal microdomains. (a) Electron microscopy of a synapse. The postsynaptic terminal is located on a dendritic spine (S) branched in the dendrite (D). Located around the axon (A) are the glial cells (G). (b) Three-dimensional EM reconstruction of two dendrites from the

hippocampus. The PSDs of excitatory synapses are marked in red and of inhibitory synapses in blue. Filopodia (marked F) and mushroom spines (marked M) are clearly seen. (c) All possible types of the dendritic spines, for example, a 3D reconstructed hippocampal dendrite, 3 weeks old in primary culture

Lennard-Jones-type repulsions, $U_{LJ}(\tilde{\mathbf{x}})$ (that represents the finite size of the ions). The force per unit mass on the i -th ion is

$$\mathbf{F}_i(\tilde{\mathbf{x}}) = -z_i e \nabla \mathbf{x}_i [U_0(\mathbf{x}_i) + U_{ii}(\tilde{\mathbf{x}})] - \nabla \mathbf{x}_i U_{LJ}(\tilde{\mathbf{x}}).$$

The dynamics of the i -th ion is given by the Langevin equation

$$\begin{aligned} \ddot{\mathbf{x}}_i + \gamma_i [\dot{\mathbf{x}}_i - \mathbf{V}(\mathbf{x}_i, t)] + \mathbf{F}_i(\tilde{\mathbf{x}}) \\ = \sqrt{2\epsilon_i \gamma_i} \dot{\mathbf{w}}_i, \end{aligned} \quad (2)$$

where $\epsilon_i = k_B T / m_i$, T is the temperature, $\gamma_i = 6\pi a_i \eta_i$ is the dynamical viscosity, η_i is the viscosity coefficient per unit mass, and a_i is the radius of the ion. The frictional drag force, $-\gamma_i [\dot{\mathbf{x}}_i - \mathbf{V}(\mathbf{x}_i, t)]$, is proportional to the relative velocity of the ion and the cytoplasmic fluid. The accelerations $\dot{\mathbf{w}}_i$ represent the thermal fluctuations of the fluid. The relation between the velocity diffusion constant and the friction coefficient,

$$D_i = \frac{k_B T}{m_i \gamma_i},$$

is Einstein's fluctuation-dissipation principle (Schuss 1980). In the Smoluchowski limit of large damping (Schuss 1980) the Langevin Eq. (2) reduces to

$$\gamma_i[\dot{\mathbf{x}}_i - \mathbf{V}(\mathbf{x}_i, t)] + F_i(\tilde{\mathbf{x}}) = \sqrt{2\epsilon_i\gamma_i}\dot{\mathbf{w}}_i, \quad (3)$$

When neglecting the ion-ion interactions, we set $U_{\text{LJ}}(\tilde{\mathbf{x}}) = U_{ii}(\tilde{\mathbf{x}}) = 0$, so that Eq. 3 becomes

$$\gamma_i[\dot{\mathbf{x}}_i - \mathbf{V}(\mathbf{x}_i, t)] + \mathbf{F}(\mathbf{x}_i) = \sqrt{2\epsilon_i\gamma_i}\dot{\mathbf{w}}_i, \quad (4)$$

where

$$\mathbf{F}(\mathbf{x}_i) = z_i e \nabla \mathbf{x}_i U_0(\mathbf{x}_i).$$

Since we are interested in tracing only one species in the spine, namely, the concentration of calcium, we assume that $\gamma_i = \gamma_{\text{Ca}^{++}}, m_i = m_{\text{Ca}^{++}}, z_i = z = 2$. Under these assumptions, equations in (4) are independent and identical, so that their transition probability densities are identical. We denote the transition probability density function (pdf) of each ion by $p(\mathbf{x}, t | \mathbf{x}_0, t_0)$ so that the calcium concentration is

$$c(\mathbf{x}, t) = \int_{\Omega_t} p(\mathbf{x}, t | \mathbf{x}_0, t_0) c_0(\mathbf{x}_0) d\mathbf{x}_0,$$

where $c_0(\mathbf{x}_0)$ is the initial calcium density.

Specification of the Hydrodynamic Flow

The flow of the incompressible cytoplasmic fluid in the spines is generated by the local contraction of actin-myosin complexes saturated by calcium ions. We assume that the flow field is derived from a potential $\phi(\mathbf{x}, t)$ (see, e.g., Landau and Lifshitz 1975),

$$\mathbf{V}(\mathbf{x}, t) = \nabla \phi(\mathbf{x}, t). \quad (5)$$

The incompressibility condition, $\nabla \cdot \mathbf{V}(\mathbf{x}, t) = 0$, reduces to the Laplace equation in the head $\Omega_H(t)$ of the spine at time t . The surface of the head, $\Sigma(t)$, is partitioned into the surface $\Sigma_H(t)$ of the spine head, that does include the surface common with the neck, and the cap $\Sigma_N(t)$ of the

surface of the head inside the neck, $\Sigma(t) = \Sigma_H(t) \cup \Sigma_N(t)$. The Laplace equation in $\Omega_H(t)$ is

$$\Delta \phi(\mathbf{y}, t) = 0 \quad \text{for } \mathbf{y} \in \Omega_H(t), t > 0, \quad (6)$$

with the boundary conditions

$$\begin{aligned} \left. \frac{\partial \phi(\mathbf{y}, t)}{\partial n} \right|_{\mathbf{y} \in \Sigma_H(t)} &= -V(t), \quad \left. \frac{\partial \phi(\mathbf{y}, t)}{\partial n} \right|_{\mathbf{y} \in \Sigma_N(t)} \\ &= F(V(t)), \end{aligned} \quad (7)$$

where $V(t)$ is the average velocity induced by the deformation of the head (see Eq. 8 below) (Holcman and Schuss 2004), due to the sum of all the local contractions, and $F(V(t))$ is the induced field velocity at the top of the neck $\Sigma_N(t)$: for a volume displaced per unit time equal to $4\pi R^2(t)V(t)$ in dimension 3 and $2\pi R(t)V(t)$, where $R(t)$ is the instantaneous radius of the head, then $R(t) = -V(t)$. The flux through Σ_N is $|\Sigma_N|v(t)$; hence

$$v(t) = F(V(t)) = \begin{cases} \frac{4\pi R^2(t)V(t)}{|\Sigma_N|} & \text{indimension 3} \\ \frac{2\pi R(t)V(t)}{|\Sigma_N|} & \text{indimension 2} \end{cases},$$

when the field is due to the contraction of myosin after 4 calcium ions are bound. The total number of sites bound to 4 calcium is $S^{(4)}(t)$ and can be obtained by solving a system of reaction-diffusion equations (Holcman and Schuss 2004). Finally the velocity at the boundary is given by

$$V(t) = v_Q S^{(4)}(t), \quad (8)$$

where v_Q is a constant velocity. The quantities $V(t)$ and $F(V(t))$ are stochastic processes, that are proportional to the number of saturated proteins at any given time t . The flow field can be expressed explicitly in terms of the functions $V(t)$ and $F(V(t))$ by Green's function for the Neumann problem for Poisson's equation in a sphere (or a disk) through Stokes' formula. Green's function $G(\mathbf{x}, \mathbf{y}, t)$ is the solution (defined up to a constant) of the equation

$$\begin{aligned}
-\Delta_{\mathbf{y}} G(\mathbf{x}, \mathbf{y}, t) &= \delta(\mathbf{x} - \mathbf{y}) - \frac{1}{|\Omega_0|} \quad \text{for } \mathbf{x}, \mathbf{y} \in \Omega_H(t) \\
\frac{\partial G(\mathbf{x}, \mathbf{y}, t)}{\partial n(\mathbf{y})} &= 0 \quad \text{for } \mathbf{x} \in \Omega_H(t), \mathbf{y} \in \Sigma(t).
\end{aligned}
\tag{9}$$

Multiplying Eq. 6 by $G(\mathbf{x}, \mathbf{y}, t)$ and Eq. 9 by $\phi(\mathbf{y}, t)$ and integrating with respect to $\mathbf{y}$ over the domain, using Stokes' theorem and the boundary condition (7), we get

$$\begin{aligned}
\phi(\mathbf{x}, t) &= \int_{\mathbf{y} \in \Sigma(t)} \frac{\partial \phi(\mathbf{y}, t)}{\partial n} G(\mathbf{x}, \mathbf{y}, t) dS_{\mathbf{y}} - \int_{\mathbf{y} \in \Sigma(t)} \frac{\partial G(\mathbf{x}, \mathbf{y}, t)}{\partial n} \phi(\mathbf{y}, t) dS_{\mathbf{y}} \\
&\quad + \frac{1}{V_H} \int_{\Omega_H(t)} \phi(\mathbf{y}, t) d\mathbf{y} \\
&= \int_{\mathbf{y} \in \Sigma(t)} \frac{\partial \phi(\mathbf{y}, t)}{\partial n} G(\mathbf{x}, \mathbf{y}, t) dS_{\mathbf{y}} + \frac{1}{V_H} \int_{\Omega_H(t)} \phi(\mathbf{y}, t) d\mathbf{y} \\
&= - \int_{\Sigma_H(t)} V(t) G(\mathbf{x}, \mathbf{y}, t) dS_{\mathbf{y}} + \int_{\Sigma_N(t)} F(V(t)) G(\mathbf{x}, \mathbf{y}, t) dS_{\mathbf{y}} \\
&\quad + \frac{1}{V_H} \int_{\Omega_H(t)} \phi(\mathbf{y}, t) d\mathbf{y} \\
&= -V(t) \int_{\Sigma_H(t)} G(\mathbf{x}, \mathbf{y}, t) dS_{\mathbf{y}} + F(V(t)) \int_{\Sigma_N(t)} G(\mathbf{x}, \mathbf{y}, t) dS_{\mathbf{y}} \\
&\quad + \frac{1}{V_H} \int_{\Omega_H(t)} \phi(\mathbf{y}, t) d\mathbf{y}.
\end{aligned}$$

The flow field is given by

$$\begin{aligned}
\nabla \phi(\mathbf{x}, t) &= -V(t) \int_{\Sigma_H} \nabla_{\mathbf{x}} G(\mathbf{x}, \mathbf{y}) dS_{\mathbf{y}} \\
&\quad + F(V(t)) \int_{\Sigma_N} \nabla_{\mathbf{x}} G(\mathbf{x}, \mathbf{y}) dS_{\mathbf{y}}.
\end{aligned}$$

In the neck, due to the symmetries and the uniform initial conditions, we simplify the flow field by assuming its velocity is parallel to the axis of the neck. It is given by

$$\nabla \phi(\mathbf{x}, t) = \mathbf{V}(\mathbf{x}, t) = F(V(t)) \mathbf{k},$$

where $\mathbf{k}$ is a unit vector along the axis of the neck. We note that according to Eq. 8, as the number of saturated proteins increases, the hydrodynamic flow begins to dominate the diffusion. In Holcman and Schuss (2004), and Holcman et al. (2004), we connected the strength of flow field to the number of bound myosin molecules induced by calcium. This results in nonlinear coupled partial

differential equations, that can be solved numerically by stochastic simulations.

Rate Constants and Molecular Dynamics

We shall now recall how to model chemical reactions, described by the backward- and the forward-binding rate, which are usually obtained in aqueous solution, where diffusion is not limited by space. In confined microdomains where the number of ions involved can be small, the binding rates have to be reinterpreted.

Backward-Binding Rate

The mean time that two molecules react chemically is modeled as the mean time the first molecule stays imprisoned in the potential well of the second. The random time interval between the binding and the reappearance of the binding molecule into the free state is exponentially distributed with a rate constant equal to the backward-binding reaction. The exponentially distributed waiting time for the backward reaction is based on Kramers' theory of activated barrier crossing,

as described in Matkowsky et al. (1982). Thus for transient chemical reactions, each molecule reacting with a calcium ion has two consequences: first, the molecule can become activated, and second, the time course of calcium is delayed. The unbinding events are modeled as Poissonian processes. Fixing a scale Δt , the probability to unbind is $k_b \Delta t$ (take a uniform variable and check whether it is above or below $k_b \Delta t$).

Forward-Binding Rate

The forward-binding rate K_{for} corresponds to the flux of particles to the binding sites. Contrary to the backward-binding rate, this rate does not contain local properties only, but includes the effect of the global geometry of the domain, where the chemical reaction occurs. Such a rate has been computed at equilibrium by Smoluchowski and can be converted as the effective radius R_a of a ball that mimics the binding site and so that the average probability that an ion meets such ball is equal to the forward rate. The radius is calibrated according to the formula

$$K_{\text{for}} = 2\pi R_a D [\text{Ca}^{2+}], \quad (10)$$

where $[\text{Ca}^{2+}]$ is the initial calcium concentration and D the diffusion constant. This calibration can also be used to estimate the effective radius of a binding molecule in a transient state, calibrated for the initial concentration condition. When the binding sites are located on the boundary, the narrow escape formula should be used (Holcman and Schuss 2013).

Modeling the Interaction of Calcium Ion with Surface or Receptors

We shall now specify the interaction conditions between a calcium ion and a receptor or a membrane, the model at a molecular and population level, and the physical laws that can be derived from elementary physical principles.

Absorption

Absorption at surface $\partial\Omega$ is the process by which a particle is removed after it hits $\partial\Omega$, which can be an artificial interface such as the one between the spine and the dendrite or an effective one such as a

channel. Indeed, during a simulation, when an ion hits such a surface, it disappears. In general, absorption on a surface is modeled by killing the trajectories when it encounters or passes over the surface $\partial\Omega$. Thus the probability density function to make a transition from $x \in \partial\Omega$ to any point y during time t is zero: $p(y, t|x) = 0$.

Partial Absorption

Partial absorption accounts for a probability that a particle arriving at a surface is reflected with a probability p or absorbed with probability $1 - p$. This condition can be calibrated to describe the interaction between the moving particle and the binding site of a receptor. This condition is formulated at a molecular level for stochastic simulations or with a probability density function to describe the macroscopic level. This condition is called also radiation or reactive or Robin boundary conditions and has been widely used to describe diffusion in a biological cell with chemical reactions on its surface (Andrews and Bray 2004; Batsilas et al. 2003; Berezhkovskii et al. 2004; Erban and Chapman 2007; Monine and Haugh 2005; Lamm and Schulten 1983; Tai et al. 2003; Zwanzig 1990).

Schematic Description

The overdamped Langevin equation can be written as a stochastic equation

$$\dot{x} = a(x, t) + \sqrt{2\sigma + (x, t)} \dot{w} \quad (11)$$

The process $x(t)$ defined by Eq. 11 with partially absorbing boundaries can be defined as the limit of Markovian jump processes generated by the Euler scheme

$$x_{\Delta t}(t + \Delta t) = x_{\Delta t}(t) + a(x_{\Delta t}(t), t)\Delta t + \sqrt{2\sigma(x_{\Delta t}(t), t)}\Delta + w(t, \Delta t) \quad \text{for } t \geq s \quad (12)$$

$$x_{\Delta t}(s) = x \quad (13)$$

in the interval $x > 0$, for $0 \leq t - s \leq T$, with $\Delta t = T/N$, $t - s = iT/N$ ($i = 0, 1, \dots, N$), where for each t the random variables $\Delta w(t, \Delta t)$ are normally distributed and independent with zero mean and variance Δt . In dimension one, with boundary at

0, the boundary behavior for the simulated trajectories that cross the boundary, identified by

$x_{\Delta t}(t) + a(x_{\Delta t}(t), t)\Delta t + \sqrt{2\sigma(x_{\Delta t}(t), t)}\Delta w < 0$ is described by

$$x_{\Delta t}(t + \Delta t) = \begin{cases} -(x_{\Delta t}(t) + a(x_{\Delta t}(t), t)\Delta t + \sqrt{2\sigma(x_{\Delta t}(t), t)}\Delta w) \text{ w.p. } 1 - P\sqrt{\Delta t} \\ \text{terminate trajectory otherwise.} \end{cases} \quad (14)$$

Thus the exiting trajectory is normally reflected w.p.

$$R = 1 - P\sqrt{\Delta t} \quad (15)$$

and is otherwise terminated (absorbed). The scaling of the termination probability with $\sqrt{\Delta t}$ reflects the fact that the discrete unidirectional diffusion current at any point, including the boundary, is $O(1/\sqrt{\Delta t})$ (Singer et al. 2008). This means that the number of discrete trajectories hitting or crossing the boundary in any finite time interval increases as $1/\sqrt{\Delta t}$.

Partial Reflecting Condition in Dimension Larger Than 2

The scheme (14) is generalized to diffusion with drift and anisotropic constant diffusion matrix $\sigma(t)$ in the half space, $x_1 > 0$, with partial oblique reflection. The Robin boundary condition is recovered if and only if trajectories are reflected in the direction of the unit vector

$$\mathbf{v} = \frac{\sigma \mathbf{n}}{\|\sigma \mathbf{n}\|}, \quad (16)$$

where $\mathbf{n}$ is the unit normal to the boundary. The radiation parameter $k(\mathbf{x}, t)$ in the d -dimensional Robin boundary condition and the absorption parameter

$P(\mathbf{x})$ are related by

$$\kappa(\mathbf{x}, t) = rP(\mathbf{x})\sqrt{\sigma_n(t)}, \quad x_1 = 0, \quad (17)$$

with $r = 1/\sqrt{\pi}$ and $\sigma_n(t) = \mathbf{n}^T \sigma(t) \mathbf{n}$. The relation (17) can also be adapted for curved boundaries and applied to the tangent plane at each point of the boundary. Indeed this is due to the fact that a smooth local mapping of the domain to a half

space with an orthogonal system of coordinates preserves the constant isotropic diffusion matrix, though the drift changes according to Itô's formula. In this case the vector $\mathbf{v}$ coincides with the normal $\mathbf{n}$.

The reflection law and the relation are new for diffusion in higher dimensions. The constant r for the Euler scheme is not the same as that for other schemes, e.g., for a discrete random walk with radiation boundaries, $r = 1/\sqrt{2}$. The reflection can be constructed explicitly. Indeed, the d -dimensional stochastic dynamic is

$$\dot{\mathbf{x}} = \mathbf{a}(\mathbf{x}, t) + \sqrt{2}\mathbf{B}(t)\dot{\mathbf{w}} \quad (18)$$

in the half space

$$\Omega = \{\mathbf{x} = (x_1, x_2, \dots, x_d) \in \mathbb{R}^d : x_1 > 0\}$$

where $\mathbf{w}$ is a vector of d independent Brownian motions and when we assume that the diffusion tensor $\sigma(t) = \mathbf{B}(t)\mathbf{B}^T(t)$ is uniformly positive definite for all $t \geq s$. We use henceforward the abbreviation $\sigma(t) = \sigma$. The radiation condition (35) becomes

$$-\mathbf{J}(\mathbf{y}, t|\mathbf{x}, s) \cdot \mathbf{n} = \kappa(\mathbf{y}, t)p(\mathbf{y}, t|\mathbf{x}, s), \text{ for } \mathbf{y} \in \partial\Omega, \mathbf{x} \in \Omega, \quad (19)$$

where the components of the flux vector $\mathbf{J}(\mathbf{y}, t|\mathbf{x}, s)$ are defined by

$$\begin{aligned} \mathbf{J}^k(\mathbf{y}, t|\mathbf{x}, s) = & -[a^k(\mathbf{y}, t)p(\mathbf{y}, t|\mathbf{x}, s)] \\ & + \sum_{j=1}^d \frac{\partial}{\partial y_j} [\sigma^{jk}p(\mathbf{y}, t|\mathbf{x}, s)] \end{aligned} \quad (20)$$

The Fokker-Planck equation for the pdf of $\mathbf{x}(t)$ can be written as

$$\frac{\partial p(\mathbf{y}, t | \mathbf{x}, s)}{\partial t} = -\nabla \mathbf{y} \cdot \mathbf{J}(\mathbf{y}, t | \mathbf{x}, s) \text{ for all } \mathbf{y}, \mathbf{x} \in \Omega \quad (21)$$

If $\mathbf{x} \in \Omega$, but

$$\mathbf{x}' = \mathbf{x} + \mathbf{a}(\mathbf{x}, t)\Delta t + \sqrt{2}\mathbf{B}(t)\Delta \mathbf{w}(t, \Delta t) \notin \Omega,$$

the Euler scheme for Eq. 18 with oblique reflection in $\partial\Omega$ reflects the point $\mathbf{x}'$ obliquely in the constant direction of $\mathbf{v}$ to a point $\mathbf{x}'' \in \Omega$, as described below. First, we denote by $\mathbf{x}_B'$ the normal projection of a point $\mathbf{x}'$ on $\partial\Omega$, that is, $\mathbf{x}_B' = \mathbf{x}' - (\mathbf{x}' \cdot \mathbf{n})\mathbf{n}$. Then we write the Euler scheme for Eq. 18 with partially reflecting boundary as

$$\mathbf{x}(t + \Delta t) = \begin{cases} \mathbf{x}' & \text{for } \mathbf{x}' \in \Omega \\ \mathbf{x}'' \text{ w.p. } 1 - P(\mathbf{x}_B')\sqrt{\Delta t}, & \text{if } \mathbf{x}' \notin \Omega, \\ \text{terminate trajectory w.p. } P(\mathbf{x}_B')\sqrt{\Delta t}, & \text{if } \mathbf{x}' \notin \Omega \end{cases} \quad (22)$$

The value of the termination probability $P(\mathbf{x}_B')\sqrt{\Delta t}$, that varies continuously in the boundary, is evaluated at the normal projection of the point $\mathbf{x}'$ on the boundary. The oblique reflection in the direction of the unit vector $\mathbf{v}$ ($v_1 \neq 0$) is defined by

$$\mathbf{x}'' = \mathbf{x}' - \frac{2x_1'}{v_1} \mathbf{v}. \quad (23)$$

Note that $x_1'' = -x_1'$ guarantees that the reflected point of a crossing trajectory is inside the domain Ω . The fact that the normal components of $\mathbf{x}''$ and $\mathbf{x}'$ are of equal lengths makes the high-dimensional boundary layer analysis similar to that in one dimension. Normal reflection corresponds to $\mathbf{v} = \mathbf{n} = (1, 0, \dots, 0)$. We note that for a point $\mathbf{y} \in \Omega$, we can write $\Pr\{\mathbf{x}'' = \mathbf{y}\} = \Pr\{\mathbf{x}' = \mathbf{y}'\}$, where

$$\mathbf{y} = \mathbf{y}' - \frac{2\mathbf{y}' \cdot \mathbf{n}}{v_1} \mathbf{v} \quad (24)$$

is the oblique reflection of $\mathbf{y}'$ (see Fig. 2). If the scheme described above is not used, a paradox can arise (Singer et al. 2008): while the pdf of the

Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis, Fig. 2

Reflection Scheme. A simulated trajectory can get from $\mathbf{x}$ to $\mathbf{y}$ in a single time step Δt in two different ways: (i) directly from $\mathbf{x}$ to $\mathbf{y}$, without crossing the boundary, and (ii) by crossing the boundary from $\mathbf{x}$ to $\mathbf{y}'$ and reflection in the oblique direction $\mathbf{v}$ with probability $1 - P(\mathbf{y}_B')\sqrt{\Delta t}$ to $\mathbf{y}$. The reflection law Eqs. 22–24 satisfies $v_1' = -v_1$

solution of Eqs. 12 and 13 converges to the solution of the FPE Eq. 32 and the initial condition Eq. 34, it does not satisfy the boundary condition Eq. 35, leading to a boundary layer, due to the diffusion approximations in the Markovian jump process (Fig. 3).

Generic Modeling of Calcium Ions at Pumps or Exchangers

Partial absorbing boundary condition can be used to model the behavior of calcium ion near a channel or a pump. However cooperativity should be implemented for each case at hand. For example, after entering inside an exchanger, an ion takes a certain time to exit: this is modeled by changing a partial reflecting boundary condition to a reflecting one as long as the ion is inside the exchanger.

Some pumps can work with several ions. As the intrinsic biophysical mechanism of permeability is not necessarily understood, there is no consensus for a universal coarse-graining scheme of

Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis, Fig. 3 The filling of space by five random trajectories in the spine with no drift (a) and with drift (b). Each color corresponds to a trajectory. Proteins are uniformly distributed in the spine head and are represented by circles and crossed circles, respectively. A trajectory starts at the top of

the spine head where channels are located and continues until it is terminated at the dendritic shaft or at an active pump. The parameters for the simulation are $\delta_1 = 0.02 \mu\text{m}$, $\delta_2 = 0.01 \mu\text{m}$, $K_{\text{back}}^{\text{AM}} = 10^4 \text{ s}^{-1}$, $K_{\text{back}}^{\text{cal}} = 2.10^3 \text{ s}^{-1}$, $R = 0.5 \mu\text{m}$, $d/2 = 0.21794 \mu\text{m}$, $l = 1.5 \mu\text{m}$, $N_{\text{pumps}} = 10$

ion extrusion. If two ions are required, we propose that once the first ion enters the channel, it cannot move before another has hit the binding area. If the second ion enters while the first one is not returned (after an exponential waiting time), then the first one can be extruded. During that time, no other ions can enter the channel.

Modeling Calcium Influx from Channels: NMDA Receptors, AMPA Receptors, and VSCC

We shall now present examples of three classical channels such as NMDA, AMPAR (GluR2-calcium permeable), and voltage-sensitive calcium channel (VSCC) for simulating the flux of calcium inside neuronal cells. The flow of ions through open channels has been studied using Langevin equation (Eisenberg et al. 1995; Roux et al. 1995). The fluxes of ions can be implemented numerically as follows.

Calcium Influx Through NMDAR

Calcium influx through NMDA channels can be approximated by (Koch 1999, p. 99)

$$I_N(t) = g_N \frac{e^{-t/\tau_{N,1}} - e^{-t/\tau_{N,2}}}{1 + 0.33[Mg^{2+}]e^{-0.06V_m}} \times (V_m - E_N), \quad (25)$$

where the conductance is $g_N = 0.16 \text{ nS}$ and the Nernst potential $E_n = 0$, V_m is the membrane potential. When the potential V_m is fixed and the fraction of current carried by calcium ions is 15%, we can simulate such a flux by injecting particles at random times such that the instantaneous rate is the one obtained from relation Eq. 25. Indeed, the entrance is a Poissonian process with a time-dependent rate $\lambda(t + \Delta t) = \frac{I_{\text{Ca}}(t)\Delta t}{2e}$. The number of entering ions is $N(t)\Delta t = \frac{I_{\text{Ca}}(t)\Delta t}{2e}$, where

Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis, Fig. 4 Calcium entry and dynamics. (a) Time course of calcium entry inside a spine through an NMDA receptor.

$I_{Ca}(t)\Delta t = \int_t^{t+\Delta t} I_N(s)ds$. An example of stochastic calcium ion entry is presented in Fig. 4 (discretized at a time step $\Delta t = 0.1$ ms). In some dendritic spine models (Holcman et al. 2004; Holcman and Schuss 2004), the entrance dynamics is neglected and ions are initially placed at channels, located at the top of the dendritic spine head. Typically, the total charge is $Q_N = \int_0^\infty I(s) ds$; thus the fraction of calcium is $Q_{Ca} = 0.15 Q_N$ Coulomb. The number of calcium ions entering is $N_{N,Ca} = \frac{Q_{Ca}}{2e}$, where the e is the electron charge. Using parameters of Table 1, we obtain that $Q_N = 6.38pC$ and thus there are about $N_{N,Ca} = 3000$ ions entering in average inside a single NMDA receptor (for a fixed mean voltage $V_m = -65.1$ mV).

Calcium Influx Through AMPAR

The stochastic arrival of ions entering through an AMPAR is computed exactly with the same method as for NMDA, except that the mean flux is given by

$$I_A = g_A \frac{t}{\tau_A} e^{-t/\tau_A} (V_m - E_A), \tag{26}$$

(b) Schematic representation of the calcium and calmodulin (CaM) pathway inside a dendritic spine (Guerrier and Holcman 2014a)

Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis, Table 1 Calcium entry into dendritic spines

Parameter	Description	Value
	Fraction of NMDAR current carried by Ca^{2+}	15%
	Total charge entering I_N (NMDAR)	6.38×10^{-15} C
	Calcium ions entering through NMDAR	≈ 3000 ions
g_N	NMDAR conductance	0.16 nS
E_N	Equilibrium potential (NMDAR)	0 mV
$\tau_{N,1}$	NMDAR time constant	11.5 ms
$\tau_{N,2}$	NMDAR time constant	0.67 ms
	Fraction of AMPAR current carried by Ca^{2+}	1.4%
	Total charge entering I_A (NMDAR)	11.51×10^{-15} C
	Calcium ions entering through NMDAR	≈ 500 ions
g_A	Conductance (AMPA)	0.3 nS
E_A	Equilibrium potential (AMPA)	0 mV
τ_A	AMPA time constant	0.2 ms
	Total charge entering I_V (NMDAR)	0.64×10^{-15} C
	Calcium ions entering through VSCC	≈ 2000 ions

where $g_A = 0.3$ nS and the Nernst potential $E_a = 0$ mV. The fraction of AMPAR current carried by calcium ions is 1.4%; thus we find that the total charge is $Q_A = 11.51$ fC, leading to approximately 500 ions.

Influx Through VSCC

Calcium influx through VSCC requires computing the changes in the membrane potential depolarization. One possibility is to use the simplified Hodgkin-Huxley model (Hille 2001). The voltage change follows the dynamics

$$C \frac{dV}{dt} = -I_{Na}(V, n) - I_K(V, n) - I_L(V) \\ - I_{Ca}(V, m, h) - \gamma I_N - \eta I_A \\ \frac{dx}{dt} = 0.1\alpha_x(1-x) - \beta_x x, \text{ for } x = n, m, h.$$

where the currents are

$$I_{Na} = g_{Na}p^3(0.89 - 1.1n)(V - E_{Na}) \\ I_K = g_Kn^4(V - E_K) \\ I_{Ca} = g_{Ca}m^3h(V_m - E_{Ca}) \\ I_L = g_L(V - E_L)$$

with parameters

$$p = \frac{\alpha_p}{\alpha_p + \beta_p}, \alpha_k = \frac{1}{\tau_k} \frac{\theta_k - V_m}{e^{\frac{\theta_k - V_m}{\tau_k}} - 1}, \\ \beta_k = \eta_k e^{\frac{V_m + 65}{\sigma_k}}, \text{ for } k = n, m, h, p.$$

where γ and η are summarized in Table 1. The total charge becomes $Q_V = 0.6$ fC, which leads approximately to 2000 ions entering through VSCC.

Stochastic Simulation of Calcium in a Dendritic Spine

The major benefit of stochastic simulations is to access the total number of biochemical bonds induced by calcium ions on specific molecules and to quantify the amount of structural changes occurring at the spine level. There are many other consequences such as computing the hydrodynamic component that changes the nature of the

ion trajectories or distinguishing the periods of calcium dynamics. Novel coarse-grained equations are derived in (Holcman and Schuss 2004).

Space Exploration

The geometric characteristics of ionic trajectories with the hydrodynamic flow are distributed differently from pure diffusion (Holcman and Schuss 2004) (see Fig. 3). Not only the nature of the movement is different, but the hydrodynamic flow causes the ions to drift in the direction of the neck, and consequently the time they spend in the spine head is reduced. As a consequence, the probability of a trajectory to leave through a pump located in the head decreases. Similarly, the probability to return to the head from the spine neck is reduced if it has to diffuse upstream, against the hydrodynamic drag force. Thus the ionic trajectory stays inside the spine a shorter time in the presence of the hydrodynamic flow, as compared to the time without it. As discussed in (Holcman et al. 2004), the total number of bound molecules can change as much as 30% with and without the flow.

Two Stages of Calcium Concentration Decay

Two very distinct decay rates of the fast extrusion periods have been reported in (Majewska et al. 2000; Sabatini et al. 2001). The second decay period is identified as purely driven by random movement, and the time constant equals the first eigenvalue of the Laplacian on the spine domain, with the adequate boundary conditions. It was shown that the first period corresponds to a fast calcium extrusion, measured in (Majewska et al. 2000) with an exponential decay rate $\lambda = 0.14$ s⁻¹ and is due to the diffusion of saturated buffers, binding kinetics of endogenous buffers, diffusion of buffers, buffered calcium diffusion across the spine neck, and the effect of the pumps. The first period dynamics is defined by the fast binding to calcium stores (Majewska et al. 2000; Sabatini et al. 2001). On the other hand, in the simulation resulting from the model (Holcman et al. 2004), based on fast spine motility, the first time period has an exponential decay rate, constant $\lambda_t = 0.16$ s⁻¹ derived in Holcman and Schuss (2004). The decay seems to be a consequence of the

dynamics created by the push effect, since stores were neglected. Further studies that include large numbers of buffers should reveal the precise contribution of buffers to the calcium fast decay rate, as compared to the rate imposed by the spine contraction.

Multiscale Modeling of Connecting a Continuum Bath with Single Molecular Dynamics

There are various interesting multiscale modeling approaches where the goal is to connect a discreet description of Brownian particles with a continuum (Franz et al. 2013; Flegg et al. 2012). The conservation of fluxes at the connecting interface generates boundary layer behavior that needs to be specifically studied.

Recipe for a Successful Stochastic Simulation

- **Choosing a time step for a simulation.** The time step of a simulation is critical: when it is too small, the simulations take forever, while if it is too large, then binding to buffers of a certain size a is missed. For a time step Δt and a diffusion coefficient D , a Brownian particle moving in three dimensions jumps to a distance $\Delta x^2 = 6D\Delta t$. Thus the constraint $|\Delta x| = a/4$ provides an estimate for the time step. In general the size of the smallest target defines the condition for the time step Δt . In most cases, where target sites are fixed, it is more interesting to refine the time step when a particle enters its neighborhood.
- **Positioning a particle that has unbound.** In the Smoluchowski limit equation (where there is no dynamic for the velocity), the coarse graining of a potential well is usually done by freezing the position of the particle at the binding position during an exponential waiting time, the rate of which is the backward rate (reciprocal of the mean time to escape the well). After the particle unbinding, where should the particle be positioned? Certainly not at the absorbing boundary defining the well; otherwise the particle is immediately absorbed, unless the boundary condition is changed from absorbing to reflecting during a certain refractory time. Another possibility is to position the particle outside the boundary

layer of the binding site: a small distance away from the site (3–4 radii away). This is possible if the sites are not surrounded by other absorbing sites. Inside a structure that contains a high concentration of binding sites, a different simulation approach is needed: either to derive a homogenized equation or the dynamics in the wells should not be coarse grained.

- **Partial absorption.** When there are many absorbing sites located at close proximity, non-linear effects should be taken into account. It is possible to derive homogenized boundary conditions (see for details (Taflia and Holcman 2011)).
- **Coarse graining a simulation with the narrow escape rate.** Instead of running a full Brownian simulation where the position of each calcium ion and calmodulin molecule is computed with the Euler scheme, it is possible to coarse grain it into a rate model based on the narrow escape theory (Schuss and Holcman 2013; Holcman and Schuss 2013). The gain of this procedure is to avoid lengthy simulation imposed by the smallest length. In a Brownian simulation, due to the small calmodulin-binding site of radius $R_{\text{CaM}} = 2$ nm, in order to ensure that the process does not jump over the site, the MSD formula leads to a time step of 10^{-6} ms (with $D_{\text{Ca}} = 200 \mu\text{m}^2 \text{ms}^{-1}$), which would lead to days of simulations. To circumvent this difficulty, it is possible to compute directly the rate of arrival of calcium ions to one of the free calmodulin-binding sites. The mean first binding time τ_B of a Brownian particle diffusing with diffusion coefficient D_I in a spherical domain Ω , to a small spherical target (radius r) diffusing with coefficient $\tau_B = \frac{|\Omega|}{4\pi(D_1+D_2)r}$. Due to the small size r , the binding times are exponentially distributed with a mean $\lambda_1 = 1/\tau_B$. For N -independent calcium ions diffusing within Ω , the first binding time T_b to a calmodulin site is distributed with rate

$$\lambda(N) = \lambda_1 N. \quad (27)$$

Thus, the probability that a binding event occurs between time t and $t + \Delta t$ is $\mathbb{P}(t \leq T_b < t +$

Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis, Fig. 5 Calcium dynamics: comparing a Brownian simulation with a coarse-grained rate model for binding to calmodulin. **A₁** and **A₂**: Time course of calcium for 3000 ions entering a dendritic spine through NMDA receptors containing 200 calmodulin. The Brownian time step is $\Delta t = 3 \cdot 10^{-6}$ ms (**A₁**). For the rate model, $\Delta t = 10^{-4}$ ms (**A₂**). Ions diffuse freely in the synapse (*dark blue*), can be

bound to calmodulin (*magenta*), or can leave the spine (*green*). The curves are compared with the total number of ions (*black*) and the total amount of calcium in the spine (free plus bound) (*in red*). **B₁** and **B₂**: Activation of calmodulin during the Brownian simulation (**B₁**) and the rate model (**B₂**). A calmodulin molecule can have zero, one, two, three, or four calcium ions bound (*black, dark blue, green, magenta, and red* respectively)

$\Delta t) = \lambda(N)\Delta t$. An application consists in replacing the Brownian movement of calcium ions in a spine head by the binding rate $\lambda(N)\Delta t$ at each calmodulin site. We thus need to compute at each time step the number N of free calcium in the spine. Furthermore, calcium ions can escape a dendritic spine head Ω_{head} through small pumps. To model this calcium escape, we use a similar method as described above where we approximate the binding of calcium to a pump by using the mean first passage time of a diffusing ion to a

small target located on the boundary. When there are N calcium ions, the first binding time is

$$\mu(N) = \frac{4R_{\text{pump}}D_{\text{Ca}}N}{|\Omega|_{\text{head}}}. \quad (28)$$

It is also possible to account for the competition with escaping through the spine neck using the narrow escape formula for a spine (Eq. 45). This procedure accelerates the simulations and gives excellent results (Fig. 5).

In Figs. 4 and 5, we present a simulation of calcium entry in a dendritic spine binding to calmodulin (Guerrier and Holcman 2014a).

Diffusion Laws in Microdomains with Small Openings

Synaptic input creates calcium transients in single dendritic spines and dendrites (Fig. 6). We shall now present the modeling approach used to study calcium transients.

Probability Density Function of an Ion

The stochastic nature of the calcium motion requires a probabilistic approach. Indeed, the

location of an ion is not certain, and the probability $p(x,t)$ to find an ion at time t at a position x satisfies the standard Fokker-Planck or diffusion equation

$$\frac{\partial p}{\partial t}(x,t) = D\Delta p(x,t), \tag{29}$$

where Δ is the Laplacian operator and D is the diffusion constant in the cytoplasm. The solution of Eq. 29 requires specifying initial and boundary conditions and allows the entire characterization of a transient regime or the steady state distribution of a single ion. For a general domain, the

Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis, Fig. 6

Upper: Isolated calcium transients in a single dendritic spine. Synaptic activity generates a transient calcium change in a spine and a whole dendritic segment, triggered by a back-propagating action potential. *Lower:* Spontaneous calcium activity in neurons. Synchronized and not synchronized activity as well as small (probably EPSPs), larger (probably single spike), and very large events (burst of several spikes). The decay phase of calcium is approximated by exponentials or sum of exponentials

solution cannot be derived analytically, but it is possible to obtain long- and short-time asymptotic estimations. As we shall see, these expressions provide the dependency with respect to many geometrical parameters. When necessary, numerical simulations are used to obtain the missing information. They are usually tedious to obtain and require careful discretization of the domain, especially when small and large scales are present.

For many independent calcium ions, the concentration $c(x, t)$ is given by $c(x, t) = Np(x, t)$, where N is the initial number of ions. Ignoring at this stage the effect of any chemical reaction, the microdomain geometry Ω is the main determinant of the characteristic time scale involved in diffusion. When the boundary decomposes into two parts, $\partial\Omega_a$ the absorbing part, made of key fast-binding elements, and $\partial\Omega_r$ the reflective part, then it is usually a critical aspect to quantify the mean time $\mathbb{E}(\tau)$ for an ion to reach $\partial\Omega_a$. The boundary conditions are

$$\begin{aligned}\frac{\partial p(x, t)}{\partial n} &= 0 \text{ on } \partial\Omega_r, \\ c(x, t) &= 0 \text{ on } \partial\Omega_a.\end{aligned}$$

The general solution of the diffusion equation can be formally expanded as

$$c(\mathbf{x}, t) = \sum_{k=1}^{\infty} c_k u_k(\mathbf{x}) \exp(-\lambda_k t) \quad (30)$$

where $\lambda_k > 0$ are the eigenvalues; u_k , $k = 1$, are the eigenfunctions; and c_k are the constants. The general explicit computation of the solution of diffusion equations can be found in Carslaw and Jaeger (1959) and Crank (1975). Although expression (30) justifies fitting a sum of exponentials to experimental data, connecting the eigenvalues with the precise geometry is in general very difficult, except in a few cases where the geometry contains a narrow passage or small hole. This is the case of a dendritic spine or a narrow domain in dendrites. When $|\partial\Omega_a| \ll |\partial\Omega_r|$, the reciprocal of the mean time to escape a domain $\mathbb{E}(\tau)d$ is the first eigenvalue (Schuss et al. 2007). Indeed, $\frac{1}{\lambda_0}$ is usually very large, so that there is a large gap

with the rest of the eigenvalue $\lambda_0 \ll \lambda_1$, and thus the solution 30 can be further approximated by a single exponential for a time $t \gg \frac{1}{\lambda_1}$,

$$c(\mathbf{x}, t) \approx c_0 \exp(-\lambda_0 t). \quad (31)$$

We conclude that for domains with narrow neck, the arrival of diffusing particles to the small domain is almost Poissonian. This is a consequence of the geometry.

Transition Probability Density Function with Partial Reflecting Boundary Condition

The transition probability density function (pdf) of the limit process 11, $p(y, t|x, s) = \Pr\{x(t) = y|x(s) = x\}$, is the solution of the FPE

$$\begin{aligned}\frac{\partial p(y, t|x, s)}{\partial t} &= -\frac{\partial[a(y, t)p(y, t|x, s)]}{\partial y} \\ &+ \frac{\partial^2[\sigma(y, t)p(y, t|x, s)]}{\partial y^2},\end{aligned} \quad (32)$$

or equivalently,

$$\frac{\partial p(y, t|x, s)}{\partial t} = -\frac{\partial J(y, t|x, s)}{\partial y} \text{ for all } y, x > 0,$$

where

$$\begin{aligned}J(y, t|x, s) &= a(y, t)p(y, t|x, s) \\ &- \frac{\partial[\sigma(y, t)p(y, t|x, s)]}{\partial y}\end{aligned} \quad (33)$$

is the flux. The initial condition is

$$p(y, t|x, s) \rightarrow \delta(y - x) \text{ as } t \downarrow s, \quad (34)$$

and the radiation boundary condition is

$$-J(0, t|x, s) = \kappa p(0, t|x, s), \quad (35)$$

where κ is a constant related to the constant c and to the values of the coefficients at the boundary. The no flux and Dirichlet boundary conditions are recovered if $\kappa = 0$ and $\kappa = \infty$, respectively. The relation between the reactive “constant” $\kappa(t)$ and the absorption parameter P for the dynamics

(Eq. 11) on the positive axis with drift and with a variable diffusion coefficient is

$$\kappa(t) = rP\sqrt{\sigma(0,t)}, \quad r = \frac{1}{\sqrt{\pi}}. \quad (36)$$

The relation Eq. 36 is true for diffusion with variable coefficients. The value $r = 1/\sqrt{\pi}$ is different than values obtained for other schemes, e.g., than the value $r = 1/\sqrt{2}$, predicted by the discrete random walk theory of radiation boundaries (Collins and Kimball 1949). Values of r for other schemes are given in Erban and Chapman (2007).

Exit Diffusion Rate from Dendritic Spines

We summarize in this section the approach used to derive asymptotic formulas for the rate of diffusional exit from the spines. A dendritic spine with a narrow neck has very degenerate geometry (Andrews and Bray 2004), but the exit time of a diffusing particle, which is the reciprocal of the first eigenvalue, can be directly measured from fluorescence imaging. We shall now recall the main formula for the exit rate that was obtained in the context of the narrow escape (NET) and dire strait (DST) theory (Holcman and Schuss 2014; Schuss and Holcman 2014).

A free Brownian particle moves in a bounded domain $D \subset \mathbb{R}^d (d = 2, 3)$, whose boundary $\partial\Omega$ is sufficiently smooth (the analysis in higher dimensions is similar to that for $d = 3$). The Brownian trajectory $x(t)$ is reflected at the boundary, except for a small hole $\partial\Omega_a$, where it is absorbed, as shown in Fig. 7. The reflecting part of the boundary is $\partial\Omega_r = \partial\Omega - \partial\Omega_a$. The lifetime in Ω of a Brownian trajectory that starts at a point $\mathbf{x} \in \Omega$ is the first passage time τ of the trajectory to the absorbing boundary $\partial\Omega_a$. The NET

$$v(\mathbf{x}) = \mathbb{E}[\tau | \mathbf{x}(0) = \mathbf{x}] \quad (37)$$

is finite under quite general conditions (Schuss 2010b). As the size (e.g., the diameter) of the absorbing hole decreases to zero, but that of the domain remains finite, the NET increases indefinitely. A measure of smallness can be chosen as the ratio between the surface area of the absorbing

boundary and that of the entire boundary, for example,

$$\varepsilon = \left(\frac{|\partial\Omega_a|}{|\partial\Omega|} \right)^{1/(d-1)} \ll 1, \quad (38)$$

provided that the isoperimetric ratio remains bounded:

$$\frac{|\partial\Omega|^{1/(d-1)}}{|\Omega|^{1/d}} = O(1) \text{ for } \varepsilon \ll 1 \quad (39)$$

The NET $v(\mathbf{x})$ can be obtained by solving the Pontryagin-Andronov-Vitt (PAV) mixed boundary value problem for Poisson's equation (Pontryagin et al. 1933; Pontryagin et al. 1989; Schuss 2010b)

$$\Delta v(\mathbf{x}) = -\frac{1}{D} \text{ for } \mathbf{x} \in \Omega \quad (40)$$

$$v(\mathbf{x}) = 0 \text{ for } \mathbf{x} \in \partial\Omega_a \quad (41)$$

$$\frac{\partial v(\mathbf{x})}{\partial n(\mathbf{x})} = 0 \text{ for } \mathbf{x} \in \partial\Omega_r, \quad (42)$$

where D is the diffusion coefficient and $\mathbf{n}(\mathbf{x})$ is the unit outer normal vector to the boundary at $\mathbf{x} \in \partial\Omega$. For a circular window of radius $a \ll |\partial\Omega|^{1/2}$ (Fig. 7),

Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis, Fig. 7 Brownian escape from a spherical window

$$\mathbb{E}_\tau = \frac{|\Omega|}{4aD \left[1 + \frac{L(0)+N(0)}{2\pi} a \log a + o(a \log a) \right]}$$

for $a \ll |\partial\Omega|^{1/2}$.

(43)

The MFPT to the absorbing boundary at the end of the funnel of a solid of revolution obtained by rotating the symmetric planar domain composed of a bulky head connected to a narrow neck formed by two tangent circular arcs of radius l_+ separated by a distance a' (see Fig. 8 in Holcman and Schuss (2013)) is given by

$$\tau = \frac{1}{\sqrt{2}} \left(\frac{l_+}{a'} \right)^{3/2} \frac{V}{l_+ D} (1 + o(1))$$

(44)

for $a' \ll l_+$,

where $V = |\Omega'|$ is the volume of the domain. The NET $\tau_{x \rightarrow \partial\Omega_a}$ of a diffusing particle from a three-dimensional domain ' Ω ' with a bottleneck in the form of a narrow circular cylinder of cross-sectional area πa^2 is given by

$$\tau_{x \rightarrow \partial\Omega_a} = \begin{cases} \frac{|\Omega_1|}{4aD} \left[1 + \frac{a}{\pi R} \log \frac{R}{a} \right] + \frac{O(1)}{D} + \frac{L^2}{2D} + \frac{|\Omega_1|L}{\pi a^2 D} & \text{solid spherical head of radius } R \text{ connected to the neck at a right angle} \\ \frac{|\Omega_1|}{4aD} \left[1 + \frac{L_2 + R_2}{2\pi} \left| \frac{\partial\Omega_a}{\pi} \right|^{1/2} \log \sqrt{\frac{|\partial\Omega_1|}{|\partial\Omega_a|}} + O \left(\sqrt{\frac{|\partial\Omega_a|}{|\partial\Omega_1|}} \log \sqrt{\frac{|\partial\Omega_a|}{|\partial\Omega_1|}} \right) \right] & \\ + \frac{L^2}{2D} + \frac{|\Omega_1|L}{\pi a^2 D} & \text{a general head connected to the neck at a right angle} \\ \frac{1}{\sqrt{2}} \left(\frac{R_c}{a} \right)^{3/2} \frac{|\Omega_1|}{R_c D} (1 + o(1)) + \frac{L^2}{2D} + \frac{|\Omega_1|L}{\pi a^2 D} & \text{a general head connected smoothly to the neck by a funnel,} \end{cases} \quad (45)$$

where R_c is the curvature at the cusp. The asymptotic expression is derived in Holcman and Schuss (2011). The order 1 term can be computed for the sphere using the explicit expression of the Neumann-Green function (Cheviakov et al. 2010). When the spine radius is small, the leading order term for the mean exit time (which is also the rate of diffusion extrusion) was initially presented in Svoboda et al. (1996). This term accounts for the many returns of an ion between the spine neck and head (Biess et al. 2007). This term is not present when an ion cannot return to the head once it enters the neck (Korkotian et al. 2004). Because the other terms in formula 45 diverge to infinity, their contribution cannot be neglected and they affect significantly the residence time of a diffusing particle in a dendritic spine (see Fig. 8). We conclude from these

analytical formulas that the spine connection determines the rate of extrusion. For short spines, all terms are significant.

Remarks

The presence of a spine apparatus inside the spine might affect the extrusion of calcium or any other diffusing molecules. In addition, molecular binding affects calcium extrusion, and the rate is no longer Poissonian.

Influence of Calcium Buffers on the Residence Time of Calcium in Microdomains Such as the Dendritic Spines

The residence of calcium in a spine can be influenced by other mechanisms than pure diffusion. Binding and unbinding to calcium buffers affect the time course. In that case, the entire

Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis, Fig. 8 Residence time of calcium in a dendritic spine.

Left: mean residence time of calcium τ_{3D} as a function of the spine radius a . *Right:* τ_{3D} is plotted as a function of the spine length L

system of partial differential equations (PDE) describing the process should be solved. Only numerical simulations are available. The generic example is

$$Ca + B_{\text{free}} \xrightleftharpoons[k_b]{k_f} Ca - B, \quad (46)$$

which leads to the PDE system of equations

$$\begin{aligned} \frac{\partial c}{\partial t}(x, t) = D\Delta c(x, t) - k_{\text{in}}c(x, t)B(x, t) \\ + k_b[c - B](x, t), \end{aligned} \quad (47)$$

$$\begin{aligned} \frac{\partial [c - B]}{\partial t}(x, t) = D_B\Delta c(x, t)B(x, t) \\ + k_{\text{in}}c(x, t)B(x, t) \\ - k_b[c - B](x, t). \end{aligned} \quad (48)$$

$c - B$ is the bound calcium that can diffuse with diffusion coefficient D_B , but stays confined in the spine head, while the calcium can be extruded at pumps or at the spine neck, which translates into the following boundary conditions:

$$\begin{aligned} \frac{\partial c(x, t)}{\partial n} &= 0 \text{ on } \partial\Omega_r, \\ c(x, t) &= 0 \text{ on } \partial\Omega_a, \\ \frac{\partial [c - B](x, t)}{\partial n} &= 0 \text{ on } \partial\Omega_r. \end{aligned}$$

when there is cooperativity at pumps, more elaborated boundary conditions are needed (Hille 2001) and will be discussed later on. There is no general solution of such equations. If binding is fast, since $c(x, t) + [c - B](x, t) = N_0 e^{-\lambda_1 t}$, the decay rate depends on the unbinding time, such that for a long enough time (so that binding occurred), the asymptotic decay rate is well approximated by a sum of two exponentials

$$c(x, t) = Ae^{-\lambda_1 t} + Be^{-k_b t}, \quad (49)$$

where A and B are constants.

Residence Time of Calcium in the Dendritic Spines with a Hydrodynamic Flow

Dendritic spines can change shape in a few hundred milliseconds (Fischer et al. 1998; Holcman

et al. 2004), after calcium ions flow in. This fast change of shape decreases the spine head volume. Spine motility was proposed by Blomberg et al. (1977), and the fast twitching movement of the spine was anticipated by F. Crick in (1982). Spine fast contraction was attributed to actin-myosin molecules or troponin C, which were observed inside the spine head. As in muscle cells, high concentrations of actin molecules indicate that rapid movement can follow the arrival of calcium ions. It has been proposed in Holcman et al. (2004) that calcium ions set the spine in motion by initiating the contraction of actin-myosin (AM) as they bind at active sites. Each molecule is assumed to give rise to a local contraction. In a simplified model, all contractions add up to achieve a global contraction, neglecting anisotropic contraction due to a delay interval between each molecule contraction. Once calcium ions enter the spine, they arrive to the binding sites by diffusion and can bind there. When four calcium ions bind to a single troponin C protein, a local contraction of the protein occurs. Adding all local contractions at a given time produces a global contraction and induces a hydrodynamic movement of the cytoplasmic fluid. Calcium trajectories are no longer pure Brownian, but contain a drift, and thus the probability to reach the dendritic shaft through the spine neck is increased (Holcman et al. 2004). The model requires feedback of a flow field $\mathbf{v}(\mathbf{x}, t)$ on the velocity. The flow field can be computed using Green's function of the spine domain (Holcman et al. 2004). Adding the effect of diffusion and hydrodynamics, the transient escape rate is not necessarily a single exponential. The concentration inside the spine follows:

$$c(x, y, z, t) = C \exp \left\{ -\lambda_1 t + \frac{\dot{v}_0^2}{4D} t \right\},$$

where the hydrodynamic decay time is

$$\tau = \frac{4D}{\dot{v}_0^2}, \quad (50)$$

where v_0 is the initial average velocity (Holcman et al. 2004). Figure 3 illustrates the effect of

adding a hydrodynamic drift on pure diffusion for the exploration of the spine head. Contrary to the effect of buffer, the hydrodynamic effect shifts the extrusion rate, but does not lead to a sum of exponentials.

Crowding Model of a Dendrite

Molecular crowding reduces diffusion, and this effect can be estimated by computing the effective diffusion coefficient of a Brownian particle moving between obstacles in dimension 2. For obstacles positioned periodically, the effective coefficient of diffusion decays nonlinearly with the density of obstacles (Holcman et al. 2011). This decay also depends on the shape of the obstacles. The effective diffusion coefficient can be computed asymptotically by conformal mapping (Holcman et al. 2011). In addition, when obstacles are positioned with additional variabilities, local narrow passages, funnels, or dead ends can be observed that lead to heterogeneity in the diffusion trajectories (Ghosh et al. 2012; Holcman and Schuss 2012, 2013). However due to the complexity of obstacle geometry, there is no achieved theory of diffusion with obstacles in three dimensions.

We present here a local model and numerical simulations to study calcium diffusion in a dendrite. The dendrite cytoplasmic medium is highly heterogeneous and filled with many organelles. Thus the motion of a diffusing particle is affected by many interactions with its environment. The functional consequences of these interactions are difficult to access directly experimentally due to ubiquitous pathways especially for calcium dynamics. In a reduced model of diffusion in dendrites, the one-dimensional effective diffusion equation and an effective diffusion constant account for the presence of heterogeneity in the medium.

Modeling Diffusion in a Heterogeneous Dendritic Cytoplasm

To characterize diffusion in a heterogeneous dendrite, containing various organelles such as mitochondria, spine apparatus, endoplasmic reticulum, and other structures, one method (Biess et al. 2011) consists of coarse graining a three-dimensional

cylindrical dendrite into a one-dimensional effective diffusion equation in the limit where the space between organelles is small. Diffusing ions can still move inside a dendritic domain Ω , and the nature of the motion is not impaired and is well approximated by the Smoluchowski limit of the Langevin equation (Schuss 2010a): a particle at position $\mathbf{X}(t)$ at time t is described by

$$\dot{\mathbf{X}} + \frac{1}{\gamma} \nabla \Phi(\mathbf{X}) = \sqrt{2D} \mathbf{w}(t), \quad (51)$$

where Φ is a potential per unit of mass, γ is the friction coefficient, D is the aqueous diffusion constant, and $\mathbf{w}(t)$ is the Gaussian white noise. The potential Φ represents the effective force on the particle. When a moving molecule hits impenetrable organelles O_i , it is reflected.

The distribution of independent molecules is characterized by the probability density function (pdf) $p(\mathbf{x}, t)$ which satisfies the Fokker-Planck equation

$$\frac{\partial p}{\partial t} = D \Delta p + \nabla \cdot \left[\frac{1}{\gamma} (\nabla \Phi(\mathbf{X})) p \right] \quad (52)$$

in the domain $\tilde{\Omega} = \Omega \setminus \cup_i O_i$ and a zero flux condition on the organelles and the dendritic membrane $\partial \tilde{\Omega}$:

$$\mathbf{J} \cdot \mathbf{n} = -D \frac{\partial p}{\partial n} + \frac{p}{\gamma} \frac{\partial \Phi}{\partial n} = 0, \quad (53)$$

where $\mathbf{J}$ is the flux and $\mathbf{n}$ the outer normal of the domain $\tilde{\Omega}$.

To account for the overall effect of crowding on diffusion, we adopt an approach based on a compartmentalization of the dendritic domain and the narrow escape theory (Holcman and Schuss 2013), which provides the mean time for a Brownian particle to exit a domain through a small absorbing opening. The dendrite is divided into periodic compartments of length l and volume V , separated from their neighbors by a reflecting cross section, except for a small opening of radius a . This compartment should be large enough so that the organelle density is the same in each of them. The small openings allow

diffusing molecules to move across compartments. In contrast to previous models where crowding has been described by spherical obstacles (Biess et al. 2011) that pose barriers to diffusing molecules, crowding is modeled as a sequence of periodic compartments and small openings at the boundaries of neighboring compartments. A compartment k starts at position x_k and ends at position x_{k+1} . The number $N_k(t)$ of particles in compartment k changes according to the net flux across the small windows. The flux is estimated by the small hole approximation (see Biess et al. (2011) for details).

The concentration $c(x, t) = N(x, t)/V(x, t)$ satisfies

$$\frac{\partial c(x, t)}{\partial t} = \frac{4l^2 D}{V(x)} \frac{\partial}{\partial x} \left[a(x) \frac{\partial}{\partial x} C(x, t) \right]. \quad (54)$$

Similar equations have been derived in other contexts (Zwanzig 1990; Biess et al. 2007; Berezhkovskii et al. 2004). When the parameters $a(x)$ and $V(x)$ are spatially independent, Eq. 54 simplifies to

$$\frac{\partial c(x, t)}{\partial t} = D_{\text{eff}} \frac{\partial^2 c(x, t)}{\partial x^2}, \quad (55)$$

where $D_{\text{eff}} = \frac{4la}{S} D$, the effective diffusion constant, and $V = Sl$, with S the cross-sectional area. The effective diffusion constant depends on two parameters: the compartment length l and the size of the opening a .

The model parameters are determined by (i) measuring the ratio of diffusion constants D_{eff}/D and (ii) a calibration condition of the form $l/a = 4$. The calibration condition expresses that the parameters l and a do not necessarily have direct physiological meanings, and we can thus set one parameter arbitrarily within the limits of the small hole approximation. Additional measurements of the diffusion constant will then fix the other parameter. A Brownian simulation of diffusing ions around an obstacle is presented in Fig. 9. Other applications of reducing equations are to compute the mean time for calcium ions or diffusing molecules to travel along crowded dendrites or axons.

Shown is the initial particle distribution as taken from the experimental data and the sampling volumes (white cylindrical disks) at

Calcium Spread Following High-Frequency Stimulation

The one-dimensional effective diffusion equation presented in the last paragraph allows analyzing calcium spread originating from localized inputs such as synapses. At dendritic synapses calcium can enter through NMDA receptors. To estimate calcium spread as a function of the synaptic input frequency, Ca^{2+} influx was simulated in the middle of a dendritic segment (Fig. 10) with buffers and pumps (see Biess et al. (2011) for the reaction-diffusion equation). The different input frequencies are $f = 5, 10, 20, 50, 80$ Hz. Interestingly, for input frequencies larger than 20 Hz, the calcium signal in the dendrite reaches a stationary value. For high input frequencies (≥ 20 Hz) calcium spread does not exceed $2.5 \mu\text{m}$ ($= 0.5 \times \text{FWHM}$) as measured from the input source. Buffers and pumps limit calcium spread to a few micrometers (Biess et al. 2011).

Calcium Extrusion Along a Cylinder: Homogenization of Hole into a Killing Rate

Computing the final distribution of calcium ions between two possible fates is a generic problem. It can be the proportion of bound calcium ions versus the number extruded or the fraction that reached the dendrite versus the fraction that got pumped. We present a general approach based on homogenization to reduce the complexity of this computation.

Homogenization of Perforated by Partially Reflecting Boundary

We approximate the flux through a reflecting boundary, perforated by many small independent absorbing holes (Berg and Purcell 1977;

Berezhkovskii et al. 2004). For diffusion, the problem can be solved using the eigenvalues of the Laplace equation in the domain Q with mixed Neumann boundary conditions on $\partial\Omega - \partial\Omega_A$ and Dirichlet conditions on $\partial\Omega_A = \cup_{i=1}^N A_i$. If the holes A_i are sufficiently far apart, the smallest eigenvalue λ_1^A is asymptotically the sum of the eigenvalues $\lambda_1^{A_i}$ of the Laplace operator in Ω with mixed Neumann-Dirichlet boundary conditions on $\partial\Omega - A_i$ and A_i , respectively, which can be calculated from the narrow escape theory (Holcman and Schuss 2013). For circular holes with fixed radius ε , we have the formula

$$\lambda_1^{A_i} \approx \frac{4\varepsilon D}{|\Omega|}, \lambda_1^A = \frac{4\varepsilon DN}{|\Omega|}. \quad (56)$$

The pdf of the Brownian motion in the perforated domain relaxes to a quasi-steady state and can be described by a single exponential decay in time with rate λ_1^A and a uniform quasi-steady state distribution in Ω , except in boundary layers near A_i . The total absorption probability flux on the boundary, λ_1^A , is partitioned among the holes with probabilities $P_i = \frac{\lambda_1^{A_i}}{\sum_{i=1}^N \lambda_1^{A_i}}$. If the holes are distributed with surface density $n(\mathbf{x})$ on $\partial\Omega$, the normal absorption flux density is

$$\mathbf{J}(\mathbf{x}) \cdot \mathbf{v}(\mathbf{x}) = \frac{4\varepsilon D n(\mathbf{x})}{|\Omega|}. \quad (57)$$

The homogenization procedure consists in replacing the perforated holes by a radiation condition that preserves asymptotically the same quasi-steady state distribution. We replace the leading eigenfunction and eigenvalue of the

(a) Calcium diffusion in an aqueous solution contained in a pipette. (b) Calcium diffusion in a crowded dendrite. The initial concentration is equal to about 600 particles and evaluates to about 470 particles per micron for a dendrite. (c) Same settings as in (a) but with additional buffers (medium buffer concentration) and pumps. (d) Same settings as in (b) but with additional buffers (medium buffer concentration) and pumps. (e) Calcium was injected at 20 Hz for 1 s at the location of the

NMDAR in the middle of the dendritic segment as shown in the upper and middle panel. The resulting spatiotemporal profile in the dendrite is shown in the lower panel. (f) Spatiotemporal profiles in the dendrite for different influx frequencies at the location of the NMDAR. (g) Corresponding calcium spread in the dendrite as measured by the full width at half maximum (FWHM) of the calcium signal. (Adapted from Biess et al. (2011)). Figure 11 shows the plot of $\tau_{\tau}^{\text{irrev}}$ for several values of the threshold T , compared to Brownian simulations in a circular disk $\Omega = D(R)$ with reflecting boundary, except at the targets

Robin problem by a Laplace equation with a small radiation function $k(\mathbf{x})$:

$$D\Delta p(\mathbf{x}) = -\lambda p(\mathbf{x}) \text{ for } \mathbf{x} \in \Omega \quad (58)$$

$$D \frac{\partial p(\mathbf{x})}{\partial \nu} = -k(\mathbf{x})p(\mathbf{x}) \text{ for } \mathbf{x} \in \partial\Omega \quad (59)$$

Matching the flux density in Eqs. 57 and 59, we obtain in dimensional coordinates

Calcium Dynamics in Neuronal Microdomains: Modeling, Stochastic Simulations, and Data Analysis, Fig. 11 The MFTT. *Left*: trajectories of diffusing molecules in a microdomain containing five binding sites on the boundary. *Right*: the time τ_T^{irrev} is plotted as a function of the threshold T . We present the Brownian

simulations (*dotted blue line*, variance in black), the theoretical formula 74 (*dotted black line*), and its approximation 75 (*continuous blue line*) for a circular disk in the irreversible case ($k_{-1} = 0$). The other parameters are $S_0 = 15$, $M_0 = 10$, $\varepsilon = 0.05$, $D = 0.1 \mu\text{m}^2\text{s}^{-1}$, and the radius of the disk $R = 1 \mu\text{m}$ (200 runs)

$$k(\mathbf{x}) = 4\varepsilon D p_o(\mathbf{x}) n(\mathbf{x}) + O\left(\frac{\varepsilon^2}{L^2} \log \frac{\varepsilon}{L}\right). \quad (60)$$

The quasi-steady state pdf is

$$p_o(\mathbf{x}) = \frac{(1 + o(k_o))}{|\Omega|},$$

except in boundary layers near A_i .

After the first homogenization which consists in replacing a three-dimensional diffusion with total and/or partial absorption by a reduced diffusion equation in dimension one, with a killing rate k , the case of a cylindrical geometry can be treated immediately. The one-dimensional case of a diffusion with uniform killing inside an interval (Holcman et al. 2005) with reflecting and absorbing endpoints has a survival pdf of a particle satisfying the equation

$$\begin{aligned} \frac{\partial p(x, t)}{\partial t} &= -\nabla \cdot J(x, t) - k p(x, t) \\ p(L, t) &= 0, p(x, 0) = \rho(x), \end{aligned} \quad (61)$$

where the probability flux density is given by

$$J(x, t) = -D \frac{\partial}{\partial x} p(x, t) + b(x) p(x, t). \quad (62)$$

For long-time asymptotic, the solution of Eq. 61 is approximated by the first eigenfunction:

$$p(x, t) = p_o(x) c^{-\lambda_o t} + O(c^{-\lambda_o t}), \quad (63)$$

normalized by

$$\int_0^L p_o(x) dx = 1 \quad (64)$$

When the killing term k is a constant, the eigenvalue problem

$$\begin{aligned} D \frac{\partial^2 p(x)}{\partial x^2} - k(x) p(x) &= -\lambda p(x) \\ p(L) &= 0, \frac{\partial p(0)}{\partial x} = 0. \end{aligned} \quad (65)$$

In case that $k(x) = k = \text{const}$, the first eigenfunction and eigenvalue are

$$p_o(x) = \Omega \frac{\cos(\Omega x)}{\sin(\Omega L)}, \Omega = \frac{\pi}{2DL}, \lambda_0 = D \frac{\pi^2}{4L^2} + k.$$

The total flux J of killed diffusing particles is given by

$$J = \int_0^L k(x)p_o(x)dx = k.$$

Particles Splitting: Absorbed Versus Arrived

To quantify how ions split between pumps located on the surface of a cylinder and the ones that arrive at the end, we use the ratio

$$\begin{aligned} R_s &= \frac{\int_{\partial\Omega_a} \mathbf{J}(\mathbf{x}|\mathbf{y}) \cdot \mathbf{v}(\mathbf{x}) dS_x}{\int_{\Omega} k(\mathbf{x}) p(\mathbf{x}|\mathbf{y}) d\mathbf{x}} \\ &= \frac{\int_{\partial\Omega_i} \Phi(\mathbf{x}) dS_x - \int_{\Omega} k(\mathbf{x}) p(\mathbf{x}|\mathbf{y}) d\mathbf{x}}{\int_{\Omega} k(\mathbf{x}) p(\mathbf{x}|\mathbf{y}) d\mathbf{x}} \end{aligned} \quad (66)$$

that can be computed in the limit of a very thin cylinder. The flux and the killing term are computed from solving the steady state using Fokker-Planck

$$0 = D\Delta p(\mathbf{x}|\mathbf{y}) - k(\mathbf{x})p(\mathbf{x}|\mathbf{y}) \text{ for } \mathbf{x}, \mathbf{y} \in \Omega \quad (67)$$

The boundary conditions are

$$\begin{aligned} p(\mathbf{x}|\mathbf{y}) &= 0 \text{ for } \mathbf{x} \in \partial\Omega, \mathbf{y} \in \Omega_a \\ \mathbf{J}(\mathbf{x}|\mathbf{y}) \cdot \mathbf{v}(\mathbf{x}) &= 0 \text{ for } \mathbf{x} \in \partial\Omega - \partial\Omega_a \\ &\quad -\partial\Omega_i, \mathbf{y} \in \Omega, t > 0. \\ \mathbf{J}(\mathbf{x}|\mathbf{y}) \cdot \mathbf{v}(\mathbf{x}) &= -\Phi(\mathbf{x}) \text{ for } \mathbf{x} \in \partial\Omega_i. \end{aligned}$$

The time-independent flux is $\Phi(\mathbf{x}) \geq 0$. The external steady-state flux of absorbed particles is

$$J_a = \int_{\partial\Omega_a} \mathbf{J}(\mathbf{x}|\mathbf{y}) \cdot \mathbf{v}(\mathbf{x}) dS_x. \quad (68)$$

The total inward flux is

$$J_i = \int_{\partial\Omega_i} \mathbf{J}(\mathbf{x}|\mathbf{y}) \cdot \mathbf{v}(\mathbf{x}) dS_x = \int_{\partial\Omega_i} \Phi(\mathbf{x}) dS_x. \quad (69)$$

If the killing measure is uniform in the interval $[0, L]$, then $R_S(L) = \frac{1}{\cosh(bL)-1}$, where $b = \sqrt{\frac{N_A}{D}}$. The case where the killing is a Dirac $k(\mathbf{x}) = k\delta(\mathbf{x} - \mathbf{x}_1)$, located at a single point $\mathbf{x}_1$, and k is a constant has been treated in Holcman et al. (2005). Interestingly, changing the distribution of killing

from uniform to concentrated at one point has a drastic effect on the final repartition of ions (see Fig. 2, Holcman et al. (2005)).

Calcium Cascade Initiating Cellular Activation

The molecular implementations that describe the transformation of a transient signal to cell activation are still unclear. We shall here present a threshold-based model: when the number of bound molecules equals a given number, we suppose that a cellular change is initiated. We present a Markov chain model that reduces the geometrical complexity based on the narrow escape rate formula (Schuss et al. 2007).

Probability to Bind a Fixed Number of Molecules During a Transient Process

To illustrate the need of a multiscale approach to bridge the molecular to the cellular scale, we recall that during long-term potentiation (LTP) induction, a transient calcium signal is converted into a long-term change in the synaptic properties (Bliss and Collingridge 1993; Malenka and Nicoll 1999; Lee et al. 2009; Lisman et al. 2012). This process specifically involves a class of kinases (CaMKII) that have complex local cooperative binding sites organized into a ring structure.

However, the first problem is to define the meaning of activation. For example, it can either be a single binding by a $\text{CaM}(\text{Ca})_3$ or $\text{CaM}(\text{Ca})_4$ molecules, several bonds, or one to six phosphorylations. Once a criterion is chosen, it becomes a computational question to estimate the probability P_k that k CaMKII molecules are activated and also compute statistical quantities such as the mean number $\langle N_{\text{act}} \rangle$ of CaMKII that are activated following a transient calcium entry.

More complicated calcium patterns are also generated where calcium ions are flowing inside a synapse. In that case, it is worthwhile to compute the number of bound molecules before an arbitrary time t or the probability $P_{\text{act}}(t)$ and the mean number $\langle N_{\text{act}}(t) \rangle$ of activations before time t . These quantities are in practice difficult to compute and depend on many parameters such as the dendritic spine geometry, the intrinsic property rate constants, the

binding site interaction forces, their localization, and so on. There are two complementary approaches:

1. **Coarse-grained Markov models:** this approach is based on the narrow escape methodology, where instead of accounting for the entire time dynamics within the complex geometry organization of the microdomain, a Poissonian rate of arrival to small targets is used to approximate the target search and finding. Various quantities of interest such as the activation probability and the statistic for the number of bound CaMKII can be estimated (Holcman and Schuss 2005; Dao Duc and Holcman 2010, 2012; Holcman et al. 2014).
2. **Brownian simulations.** Contrary to the previous approach, it is not possible to obtain the exact dependency of the probability; rather this approach is tedious and allows estimating any moment of interest for a given set of parameters.

For a microstructure such as a dendritic spine, there is no equilibrium, because the steady state is zero. Thus the relaxation time is the time for a diffusing particle to be extruded by diffusion, which is in the range of tens of ms (see Holcman and Schuss 2011). The probability for N CaMKII to be activated and the time to induction is the mean time for this to happen during a repetitive stimulation. Because the calcium to CaMKII pathways requires CaM intermediates, there is no coarse-grained model yet (Guerrier and Holcman 2014a). To present the threshold method, we shall now present a simplified model where a diffusing molecule can bind to a ligand. The probability to reach a threshold has been developed in Dao Duc and Holcman (2010) and is reviewed here briefly.

Coarse-Grained Markov Models

Traditional chemical kinetics, based on mass-action laws or reaction-diffusion equations, give

an inappropriate description of the stochastic chemical reactions in microdomains, where only a small number of substrate and reactant molecules is involved. A reduced Markovian description of the stochastic dynamics of the binding and unbinding of molecules is given in Holcman and Schuss (2005) and applied in Dao Duc and Holcman (2010, 2012). Specifically, consider two finite species, the mobile reactant M that diffuses in a bounded domain Ω and the stationary substrate S (e.g., a protein) that binds M . The boundary $\partial\Omega$ of the domain Ω is partitioned into an absorbing part $\partial\Omega_a$ (e.g., pumps, exchangers, another substrate that forms permanent bonds with M , and so on) and a reflecting part $\partial\Omega_r$ (e.g., a cell membrane). In this model, the volume of M is neglected. In terms of traditional chemical kinetics, the binding of M to S follows the law

where k_f is the forward-binding rate constant, k_b is the backward-binding rate constant, and S_{free} is the unbound substrate. We assume in our model of the reaction that the M molecules diffuse in Ω independently and, when bound, are released independently of each other at exponential waiting times with rate k_{-1} .

To calculate the average number of unbound (or bound) sites in the steady state, the following reduced model is used. The number $k(t)$ of unbound receptors at time t is a Markovian birth-death process with states $0, 1, 2, \dots, \min\{M, S\}$ and transition rates $\lambda_k \rightarrow k+1 = \lambda_k$, $\lambda_k \rightarrow k-1 = \mu = k_{-1}$. The boundary conditions are $\lambda_S \rightarrow S+1 = 0$ and $\lambda_0 \rightarrow -1 = 0$. Setting $P_k(t) = \Pr\{k(t) = k\}$, the Kolmogorov equations for the transition probabilities are given by (Holcman and Schuss 2005).

$$\begin{aligned} \dot{P}_k(t) = & -[\lambda_k + k_{-1}(S - k)]P_k(t) + \lambda_{k+1}P_{k+1}(t) + k_{-1}(S - k + 1)P_{k-1}(t) \\ \text{for } k = & (S - M)^+ + 1, \dots, S - 1 \end{aligned} \quad (71)$$

with the boundary equations

$$\begin{aligned}\dot{P}_{(S-M)^+}(t) &= -k_{-1}SP_{(S-M)^+}(t) + \lambda_1 P_{(S-M)^++1}(t) \\ \dot{P}_S(t) &= -\lambda_S P_S(t) + k_{-1}P_{S-1}(t)\end{aligned}$$

and initial condition $P_{k,q}(0) = \delta_{k,S}\delta_{q,0}$. In the limit $t \rightarrow \infty$ to the model (71) gives the average number

$$\langle k_\infty \rangle = \sum_{j=(S-M)^+}^S jP_j,$$

where $P_j = \lim_{t \rightarrow \infty} P_j(t)$. Similarly, the stationary variance of the number of unbound sites is $\sigma^2(M, S) = \langle k_\infty^2 \rangle - \langle k_\infty \rangle^2$, where $\langle k_\infty^2 \rangle = \sum_{j=(S-M)^+}^S j^2 P_j$. The rates λ_k are modeled as follows. For a single diffusing molecule, the time to binding is the first passage time to reach a small absorbing portion $\partial\Omega_a$ of the boundary, which represents the active surface of the receptor, whereas the remaining part of $\partial\Omega$ is reflecting. Due to the small target and to the deep binding potential well, the binding and unbinding of M to S are rare events on the time scale of diffusion (Schuss et al. 2007). This implies that the probability distribution of binding times is approximately exponential (Schuss 2010b) with rate $\lambda_1 = 1/\mathbb{E}\tau_1$, where the NET $\mathbb{E}\tau_1$ is the MFPT to $\partial\Omega_a$. When there are S binding sites, $k(t)$ of which are unbound, there are $N = [M - S + k]^+$ free diffusing molecules in Ω , where $x^+ = \max\{0, x\}$. The arrival time of a molecule to the next unbound site is well approximated by an exponential law with state-dependent instantaneous rate (see discussion in Holcman and Schuss (2005))

$$\lambda_k = \frac{Nk}{\mathbb{E}\tau_1} = \frac{k(M - S + k)^+}{\mathbb{E}\tau_1}.$$

The results of the Markovian model (71) are

$$\begin{aligned}P_S &= \frac{1}{1 + \sum_{k=1}^{S-(S-M)^+} \frac{\prod_{i=S-k+1}^S i(M - S + i)^+}{k!(\mathbb{E}\tau_1 k_{-1})^k}} \\ \langle k_\infty \rangle &= P_S \sum_{k=S-1}^{(S-M)^+} (S - k)^+ \frac{\prod_{i=S-k+1}^S i(M - S + i)^+}{k!(\mathbb{E}\tau_1 k_{-1})^k} \\ \langle k_\infty^2 \rangle &= P_S \sum_{k=S-1}^{(S-M)^+} [(S - k)^+]^2 \frac{\prod_{i=S-k+1}^S i(M - S + i)^+}{k!(\mathbb{E}\tau_1 k_{-1})^k} \\ \sigma_S^2(M) &= \langle k_\infty^2 \rangle - \langle k_\infty \rangle^2\end{aligned}\tag{72}$$

(see Holcman and Schuss (2005) for further details).

These formulas are used to estimate the fraction of bound receptors in photoreceptor outer segments and also to interpret the channel noise measurement variance in Holcman and Schuss (2005). In Holcman and Triller (2006) this analysis was used to estimate the number of bound AMPA receptors in the postsynaptic density. A similar gated Markovian model was proposed in Bressloff and Earnshaw (2009).

The reduced Markovian model is used for the calculation of the mean time of the number of bound molecules to reach a given threshold T (MFTT). In a cellular context, the MFTT can be used to characterize the stability of chemical processes, especially when they underlie a biological function. Using the above Markov chain description, the MFTT can be expressed in terms of fundamental parameters, such as the number of molecules and ligands and the forward- and backward-binding rates. It turns out that the MFTT depends nonlinearly on the threshold T . Specifically consider M Brownian molecules that can bind to immobile targets S inside a microdomain, modeled generically by Eq. 70. The first time the number $[MS](t)$ of MS molecules at time t reaches the threshold is defined as

$$\tau_T = \inf \{t > 0 : [M|S](t) = T\},\tag{73}$$

and its expected value is τ_T . Consider the case of an ensemble of the targets initially free and distributed on the surface of a closed microdomain and assume that the backward rate vanishes ($k_{-1} = 0$) and $k_f > 0$. The dynamical system for the transition probabilities of the Markov process $MS(t)$ is similar to that above, but for the absorbing boundary condition at the threshold T , which gives Eq. 71 (Dao Duc and Holcman 2010). When the binding is irreversible ($k_{-1} = 0$), τ_T is the sum of the forward rates

$$\begin{aligned}\tau_T^{\text{irrev}} &= \frac{1}{\lambda_0} + \frac{1}{\lambda_1} + \dots + \frac{1}{\lambda_{T-1}} \\ &= \frac{1}{\lambda} \sum_{k=0}^{T-1} \frac{1}{(M_0 - k)(S_0 - k)}\end{aligned}\tag{74}$$

In particular, when $M_0 = S_0$ and $M_0 \gg 1$, Eq. 74 becomes asymptotically $\tau_T^{\text{irrev}} \approx T/\lambda$ ($M_0(M_0 - T)$). In addition, when the number of

diffusing molecules greatly exceeds the number of targets ($M_0 \gg S_0, T$), (74) gives the asymptotic formulas

$$\tau_T^{\text{irrev}} \approx \begin{cases} \frac{1}{\lambda M_0} \log \frac{S_0}{S_0 - T} & \text{for } M_0 \gg S_0, T \\ \frac{1}{\lambda S_0} \log \frac{M_0}{M_0 - T} & \text{for } S_0 \gg M_0, T \\ \frac{T}{\lambda M_0 S_0} & \text{for } M_0, S_0 \gg T. \end{cases} \quad (75)$$

Discussion and Conclusion

We have summarized here biophysical models at a molecular level, mathematical analysis, and coarse-graining models to study calcium dynamics in cellular microdomains. The present approach can be implemented to better understand how calcium dynamics can induce sophisticated processes such as long-term potentiation or depression, cellular process that are responsible for long-lasting changes in physiological properties. Yet what calcium is doing at synapses still remains unclear: where calcium is accumulating, what is the number of activated CaMKII (it is not exactly clear what is the meaning of being activated; it can be that a single site is phosphorylated), and what other calcium-activated molecules are important. We presented as an example of complex calcium feedback how spine twitching can be described at a molecular level. We also described Brownian and simplified simulation of calcium and the CaMKII pathway. The CaMKII molecule can be modeled as a simplified ring made of six balls. A calibration procedure is then use to determine the radius a of a sphere or disk in that matches the Smoluchowski formula. We have not reviewed the presynaptic terminal, which is a critical microdomain where calcium modulates the release of vesicles. Vesicular release is triggered by calcium entrance at specific calcium channels (Holderith et al. 2013). The exact steps from the calcium entrance to the vesicular release are still under investigation. The steps of calcium diffusion have been investigated both experimentally and numerically. In particular the distance from the channel to the vesicle is a

key parameter. Channel clustering also would be interesting to investigate. The possibility that channels are not fixed and the membrane is constantly remodeled shows that this process is quite complex. Interestingly, the release probability can be modulated by six orders of magnitude (Kochubey et al. 2011; Schneggenburger et al. 2012). Simulations of presynaptic calcium are based on numerically solving partial differential equations (Matveev et al. 2004; Zucker and Regehr 2002; Zucker 1993); however, it is hard to account for the cusp nature of the region between the vesicles and the plasma membrane (Neher 2010). Analyzing diffusion in cusps can be studied by mapping locally the cusp conformally to a nonsingular domain or to use analytical computation (Holcman and Schuss 2012; Guerrier and Holcman 2014b). Another difficulty is to account for various varicosities, leading to divergences, and a multiscale analysis should be developed. Modeling approaches are already shedding a new light on the unsolved debate about the role of the dendritic spines in regulating electrical versus chemical activity. It is certainly time to revisit the electrical properties of the spines based on solving the full Poisson-Nernst-Planck equation. Chemical properties should consider surface receptors trafficking as a chemical reservoir.

Calcium Dysregulation in Neurodegenerative Diseases

Haroon Anwar

Princeton Neuroscience Institute, Princeton University, Princeton, NJ, USA

Nathan Kline Institute for Psychiatric Research, Orangeburg, NY, USA

Definition

Intracellular Ca^{2+} is controlled by a complex network of Ca^{2+} -binding proteins, voltage-gated Ca^{2+} channels (VGCC), pumps, transporters, and intracellular stores (see Fig. 1). A large number of resources allocated for proper handling of intracellular Ca^{2+} levels manifest the significance of Ca^{2+} regulation in the lifecycle of a cell. The disruption in proper handling of intracellular Ca^{2+} can alter the excitability properties and synaptic connectivity (Koffie et al. 2011; Scheff et al. 2007) resulting in a loss of functional neural networks, which may cause severe motor and cognitive disabilities (DeKosky and Scheff 1990). Furthermore, Ca^{2+} dysregulation may trigger molecular events that can eventually lead to neuronal death. Because these effects are typically observed in neurodegenerative disease, it is obvious that the malfunctioning of Ca^{2+} regulatory mechanisms is related to these disorders. In the past, many studies have proposed different hypotheses regarding disease onsets and propagation and have tried to relate the malfunctioning of Ca^{2+} handling mechanisms to the disease. However, because of interdependence of the molecular pathways, the role of individual mechanisms and the causality between Ca^{2+}

Ca²⁺ regulation under physiological conditions

Ca²⁺ dysregulation in neurodegenerative diseases

Calcium Dysregulation in Neurodegenerative Diseases, Fig. 1 A schematic comparing Ca²⁺ handling in healthy vs diseased neuron. The highlighted regions (in red) in the lower panel show enhanced cytosolic Ca²⁺ due to upregulation of Ca²⁺ permeable channels (VGCCs, AMPARs, NMDARs, RyRs), altered dynamics of these channels (indicated by thicker arrows), and addition of

Ca²⁺ leak channels in ER (m-presenilins). In response to increase in cytosolic Ca²⁺ levels, PMCA and SERCA increase their activities and need more ATP to maintain the Ca²⁺ levels in physiological range, which causes oxidative stress in mitochondria. Furthermore, enhanced Ca²⁺ transport to mitochondria has been reported in neurodegenerative diseases via MAMs and MCU

dysregulation and disease onset and propagation remains unclear. We hope that computational modeling capturing Ca^{2+} regulatory mechanisms and Ca^{2+} -dependent signaling pathways can help establish the basis of disease onset and progression and eventually could allow uncovering the possible targets for intervention and prevention.

In this chapter, first I will discuss mechanisms of Ca^{2+} dysregulation in a few neurodegenerative diseases (see Fig. 1 lower panel) and then will review existing computational models of neurodegenerative diseases with emphasis on Ca^{2+} dynamics.

Detailed Description

Mechanisms Underlying Ca^{2+} Dysregulation in Neurodegenerative Diseases

Ca^{2+} dysregulation in Alzheimer's is triggered by abnormal aggregation of beta amyloids ($\text{A}\beta$), which in turn either enhances Ca^{2+} leak from endoplasmic reticulum (ER) into cytosol (Tu et al. 2006) via mutant presenilins (Bezprozvanny 2013) or via upregulation of ryanodine receptors (RyR) (Bruno et al. 2012; Kelliher et al. 1999) or enhances mitochondrial-ER cross talk via mitochondria-associated membranes (MAMs) (Area-Gomez and Schon 2016; Area-Gomez et al. 2018; Hedskog et al. 2013). Additionally, a shift in the balance between Ca^{2+} -calmodulin-dependent kinase II (CaMKII) and Ca^{2+} -dependent phosphatase calcineurin (CaN) at the synapses may disproportionally enhance long-term depression (LTD) (Reese et al. 2011). As a result, synapses get weakened and eventually eliminated. Ca^{2+} imbalance may also be triggered by extracellular block of K^+ channels by $\text{A}\beta$ that can lower the threshold of spiking and enhances the excitability of the neuron (Good 1996). Moreover, protein aggregation and misfolding may directly or indirectly affect the Ca^{2+} permeability of VGCCs, AMPARs, and NMDARs or result in decrease affinity of plasma membrane Ca^{2+} -ATPases (PMCAs), sarco/endoplasmic reticulum Ca^{2+} -ATPases (SERCAs), Na^+ - Ca^{2+} exchangers

(NCXs), and Ca^{2+} buffers. Handling increased loads of Ca^{2+} , and breakdown of increased toxic proteins may cause oxidative stress (Aliev et al. 2014) and trigger autoimmune response (Eikelenboom et al. 2010) leading to homeostatic imbalance, loss of network connectivity, and neuronal death. More details can be found in recent review articles (Gibson 2017; Popugaeva et al. 2017; Wang et al. 2017).

In Parkinson's disease (PD), dopamine-releasing neurons within substantia nigra (SN-DA) are particularly vulnerable to the degeneration compared to other dopaminergic neurons. The Ca^{2+} regulatory mechanisms are not only crucial for the dopamine release within a physiological range but also modulate their mitochondrial (Davey and Bolaños 2013) and lysosomal activity (Tofaris 2012), their metabolic stress levels, and their vulnerability to degeneration. It is not clear what make SN-DA neurons vulnerable to PD. It has been hypothesized that low levels of Ca^{2+} -binding proteins in SN-DA neurons like calbindin increase susceptibility of these neurons to the disease. Because Ca^{2+} in SN-DA neurons is mainly removed from cytosol by uptake into ER via SERCA pumps and by mitochondria via MCU or mitochondria $\text{Ca}^{2+}/\text{H}^+$ exchanger or indirectly via MAMs (Cali et al. 2012; Guardia-Laguarta et al. 2014), slight disruption in any of the Ca^{2+} regulatory process can lead to increased Ca^{2+} levels, which can trigger downstream processes eventually leading to cell death. Recent studies have implicated aggregation of α -synuclein in enhanced activation of SERCA pumps (Betzer et al. 2018) and L-type Ca^{2+} channels in Parkinson onset (Lieberman et al. 2017) resulting in increased oxidative stress and mitochondrial dysfunctioning. More details can be found in recent review articles (Dolgacheva et al. 2018; Ludtmann and Abramov 2018; Post et al. 2018).

In Huntington's disease, GABAergic medium-sized striatal spiny projection neurons are considered to be the main target for the disease onset. In addition to synaptic dysfunction in these neurons, Huntington disease gene (Htt) alters Ca^{2+} homeostatic regulation by disrupting mitochondrial and

ER function. Htt directly interacts with the mitochondrial membrane reducing its ability to sequester Ca^{2+} (Panov et al. 2002). Bezprozvanny and colleagues showed that mutant Htt (mHtt) sensitized the $\text{IP}_3\text{R1}$ to IP_3 , thereby enhancing Ca^{2+} release in response to activation of metabotropic glutamate receptors (Tang et al. 2003). Subsequent studies indicated that inhibition of $\text{IP}_3\text{R1}$ function by genetic knockdown interfering peptides or pharmacological agents could protect striatal neurons from glutamate-mediated apoptosis (Tang et al. 2005, 2009). In a recent study, Bezprozvanny group showed that striatal dendritic spine loss could also be rescued by inhibition of the store-operated Ca^{2+} entry (SOCE), which is observed to be overactive in response to a depletion of ER Ca^{2+} stores because of the higher basal activation of $\text{IP}_3\text{R1}$ induced by mHtt (Wu et al. 2016). RyR mediate Ca^{2+} -induced Ca^{2+} release in response to influx through plasma membrane channels; however, RyR can also act as a source of Ca^{2+} “leak” into the cytosol at rest elevating the basal intracellular Ca^{2+} concentration (Guerrero-Hernández et al. 2014). In neurons, such chronic increases in intracellular Ca^{2+} can alter responsiveness of a large number of signaling pathways, shifting threshold for synaptic plasticity, survival/growth, and other signaling essential for the neurons’ role in circuit function. (Read (Mackay et al. 2018; Naia et al. 2017) for more details).

Mitochondrial dysfunction and alteration in ER-mitochondria cross talk have been observed in amyotrophic lateral sclerosis (ALS)-affected motor neurons (Cozzolino and Carri 2012) (also see review (Manfredi and Kawamata 2016)). Excessive mitochondrial Ca^{2+} accumulation can cause the opening of the mitochondrial permeability transition pore, which has been associated with activation of cell death pathways (Rasola and Bernardi 2011). It was demonstrated experimentally that altering the physical distance between the opposing membranes affect Ca^{2+} flow from ER to mitochondria and cell viability (Csordás et al. 2006). The most evident ER abnormality described in ALS is ER stress accompanied by upregulation of the unfolded protein response (UPR). This phenomenon has been amply

described in ALS patients (Kiskinis et al. 2014), as well as in cellular and animal models of ALS (Walker et al. 2013; Zhang et al. 2014). However, it is unclear what exactly triggers the activation of UPR. It is likely that proteostasis dysregulation is involved in the activation of UPR. The experimental evidence suggests that MAMs- and ER-mitochondria communications, especially lipid metabolism and Ca^{2+} signaling between the two organelles, are logical points of interaction in the pathogenesis of different forms of ALS. Decreased ER-mitochondria interaction could result in insufficient Ca^{2+} transfer from the ER stores to mitochondria and defective bioenergetic coupling. It could also alter the autophagic process, because of impaired vesicle biosynthesis. However, abnormally increased or persistent ER-mitochondria contact might result in enhanced Ca^{2+} flux into mitochondria, triggering mitochondrial permeability transition and apoptosis. RyRs could also be potentially dysregulated in ALS causing abnormal cytosolic and mitochondrial Ca^{2+} influx (Grosskreutz et al. 2010). Sensitivity to Ca^{2+} dysregulation may be affected by Ca^{2+} -binding proteins, since motor neurons have lower amount of these proteins compared to ALS-spared neurons (Bernard-Marissal et al. 2012). More details can be found in recent review articles (Bernard-Marissal et al. 2018; Raymond 2016; Smith et al. 2017).

Computational Models of Neurodegenerative Diseases with Ca^{2+} Dynamics

The existing computational models of neurodegenerative diseases lack the detailed description of mechanisms controlling intracellular Ca^{2+} levels that would be required to make these models useful for better understanding the diseases. Most of the models only validate the experimentally proposed hypothesis related to diseases. The computational models investigating the effects of synaptic dysregulation and homeostatic regulation on network connectivity (Anastasio 2014; Romani et al. 2013; Rowan et al. 2014) were too simple to extend their usefulness beyond revealing mechanistic details. Some of these models provide insights into disease onset, disease progression, and its effects on behavior of

subcellular organelles, individual neurons, and neural networks, but the results were mostly attributed to a single factor. In contrast, the neurodegenerative diseases cause disruption of many interacting processes. A few computational models of neurodegenerative diseases with Ca^{2+} dynamics captured at different scales are briefly described below.

A computational model of protein aggression developed by De Caluwé and Dupont (2013) qualitatively described the interactions between intracellular Ca^{2+} and $\text{A}\beta$. The rise and decay of intracellular Ca^{2+} and $\text{A}\beta$ level were captured by a single rate constant for each. The activation of $\text{A}\beta$ synthesis by Ca^{2+} was represented by a hill term with a maximal rate V_{ω} , half-saturation constant K_{ω} , and a Hill coefficient n . They also considered that $\text{A}\beta$ oligomers induce Ca^{2+} entry into the cell, putatively by provoking an increase in plasma membrane permeability. This process was characterized by a cooperativity coefficient m and a rate constant k_{β} . Using that model the authors showed that a “steady state” characterized by low levels of Ca^{2+} and amyloids coexist with “pathological state” where the levels of both compounds are high. Thus, a large enough perturbation in either amyloid metabolism or up regulation of Ca^{2+} homeostasis could trigger AD onset.

A model proposed by Good et al. (1996) showed in cultured hippocampal neurons that $\text{A}\beta$ could block fast inactivating K^{+} currents without affecting its kinetics. Later Good and Murphy (1996) proposed a mathematical model of hippocampal neuron showing $\text{A}\beta$ -mediated block of A-type K^{+} channels could result in increased intracellular Ca^{2+} levels and increased membrane excitability. Their model had an immobile Ca^{2+} buffer with a single binding site, a Ca^{2+} extrusion pump (using Michaelis-Menten kinetics), Ca^{2+} diffusion, and several VGCCs to regulate intracellular Ca^{2+} levels. They showed that an increase in Ca^{2+} buffering capacity or decrease in density of VGCCs could reduce the $\text{A}\beta$ -mediated effects causing less increased Ca^{2+} levels and excitability.

Morse and colleagues (Morse et al. 2010) used a multi-compartment computational model of hippocampal pyramidal neuron to show that oblique apical dendrites are more vulnerable to

$\text{A}\beta$ during back propagating action potential because of their proximity to the axosomatic region in contrast to apical tuft dendrites and the smaller dendritic diameters. The excitability of the model neuron is enhanced by $\text{A}\beta$ -mediated block of A-type K^{+} channels. The model suggested that the less attenuated back propagating action potential in oblique dendrites may activate larger number of VGCCs causing larger influx of Ca^{2+} into the cytosol, which will result into much larger concentrations of intracellular Ca^{2+} due to the larger surface-to-volume ration in oblique dendrites (Morse et al. 2010).

Only recently, some efforts were put toward constructing somewhat detailed computer model of a motor neuron linking electrical activity with ATP pathways (Le Masson et al. 2014). The model included the plasma membrane $\text{Na}^{+}/\text{K}^{+}$ ATPases, PMCA, SERCA, plasma and mitochondrial NCX, MCU, and mitochondrial dynamics for converting ADP into ATP to meet the cell's energy demands. The multi-compartmental neuron model included I_{h} , Na^{+} , K^{+} , VGCCs, and K_{Ca} channels. Using this model, the authors proposed that a reduction in ATP availability can lead the neuron to prolonged depolarization, causing massive influx of Ca^{2+} , leading to cell death. The authors showed that this process involved a positive feedback loop in which small deficits in available ATP lead to small ion imbalances that, in turn, caused a higher energy demand on the neuron, which lead to worse imbalances. This study provided theoretical evidences that bioenergetics could be a critical determinant of motor neuron differential susceptibility in ALS. Based on the findings of their model, they suggested that any therapeutic strategies aimed at supporting bioenergetics might enhance the capacity of motor neurons to withstand pathological insults, thereby prolonging the lifespan of ALS patients.

Mitochondrial dysfunction is observed in almost all neurodegenerative diseases. It is known that aggregated proteins such as $\text{A}\beta$ and α -synuclein alter the dynamics of MAMs. Malfunctioned MAM can induce ER-mitochondria cross talk. Therefore including MAM dynamics in the computational model of diseases will provide a much better understanding of the emergent

behavior of the interactions of several dysfunctional Ca^{2+} regulatory mechanisms. Such an effort has been made by Szopa and colleagues by constructing a model of ER-mitochondria cross talk to investigate its effects on Ca^{2+} oscillations (Szopa et al. 2013). This model was extended from the existing model (Marhl et al. 2000) to capture Ca^{2+} regulation by ER, mitochondria, and the interaction between ER and mitochondria. The Ca^{2+} influx into mitochondria was modeled via mitochondrial Ca^{2+} uniporters (MCU) located in MAMs sensing elevated Ca^{2+} concentrations in ER and Ca^{2+} uniporter located outside MAMs sensing cytosolic Ca^{2+} levels. The Ca^{2+} release from mitochondria into cytosol was represented by $\text{Na}^+/\text{Ca}^{2+}$ and $\text{H}^+/\text{Ca}^{2+}$ exchangers with the rate of Ca^{2+} efflux regulated by the cytosolic Ca^{2+} concentrations. The Ca^{2+} influx into ER was modeled using a SERCA pump, whereas the Ca^{2+} release into the cytosol from ER was modeled using a Ca^{2+} leak channel and $\text{IP}_3\text{Rs/RyRs}$. A single Ca^{2+} -binding protein was included in the model to bind free cytosolic Ca^{2+} . The model produced Ca^{2+} oscillations where the period of oscillations depended on the Ca^{2+} permeability through MAMs. The model predicted that for sufficiently large Ca^{2+} permeability, the oscillations disappeared resulting into high Ca^{2+} levels in mitochondria, which could be interpreted as early step in an apoptotic pathway.

Recently, Matsuzawa et al. presented a multiscale model exploring the effects of $\text{A}\beta$ on synaptic plasticity using computer simulations (Matsuzawa et al. 2017). Ca^{2+} influx was modeled using NMDA current, whereas intracellular Ca^{2+} was modeled using a simple exponential decaying pool. The parameters of a phenomenological synaptic weight model were fitted to a more realistic kinetic model of synaptic plasticity involving insertion/removal of AMPARs. Both LTP and LTD were modeled using a sigmoid function dependent on intracellular Ca^{2+} . The effect of $\text{A}\beta$ was implemented by altering the threshold of activation of LTP and LTD based on $\text{A}\beta$ concentration. The model supports the hypothesis that $\text{A}\beta$ interacts with the phosphorylation/

dephosphorylation pathways of AMPAR at multiple molecular substrates occasionally in opposing manner, eventually resulting in enhanced LTD. Another detailed model of Alzheimer's analyzes the interaction among $\text{A}\beta$ depositions, Ca^{2+} signaling and mitochondrial function was published recently (Ranjan et al. 2018). This model shows that $\text{A}\beta$ accumulation causes an increase in intracellular Ca^{2+} levels and dysregulation of Ca^{2+} channel receptors on the ER. For more details see Ranjan et al. (2018).

Conclusions

The main motivation to study neuroscience is to understand how molecular and cellular mechanisms give rise to functional neurons and neural networks underlying behavior, so that we can understand the causes of psychiatric and neurodegenerative diseases in hope to intervene and cure, prevent, or slow down its progression. The main challenge we face today is because of the ability of subcellular processes, neurons, and neural networks to self-regulate with dynamics that can adapt variably to different levels of perturbation. Because most of these homeostatic processes are Ca^{2+} dependent, it is evident that Ca^{2+} dysregulation in neurodegenerative diseases alter the dynamics of homeostatic regulation. This means that any sort of intervention would require a precise control over homeostatic regulation in the brain. Thus far, I am unaware of many studies quantifying dynamics of molecular pathways underlying homeostasis. That leaves a big space for computational neuroscientists to intervene. However, to succeed with this challenge, a community effort and collaboration with experimentalists would be required to setup a framework to properly explore the parameters and validate with experiments. Without including multiscale homeostatic regulation descriptions in computational models of diseases, these models will remain limited in their usefulness, as has been the case in the past. Future models of neurodegenerative disorders must incorporate detailed Ca^{2+}

dynamics along with the factors that cause the disease onset and the downstream signaling pathways affecting the motor control and memory and lead to psychosis.

Calcium Pumps, Models of

Kim T. Blackwell

Department of Bioengineering, George Mason University, Fairfax, VA, USA

Molecular Neuroscience Department, Krasnow Institute for Advanced Study, George Mason University, Fairfax, VA, USA

Definition

Calcium pump is the general term that refers to molecules that extrude or remove calcium from the cytosol. The calcium may be pumped into the extracellular space, or pumped into organelles such as the smooth endoplasmic reticulum or mitochondria, both of which function as calcium stores. Some of these pumps directly utilize ATP as an energy source and are known as calcium ATPases. Other pumps rely on concentration gradients and thus are exchangers.

Detailed Description

So far only three different types of calcium pumps have been used in computational models. Two of them are calcium ATPases: the smooth endoplasmic reticulum ATPase (SERCA) pump and the plasma membrane calcium ATPase (PMCA) pump (e.g., Morgans et al. 1998). Both of these are typically modeled as an enzyme reaction, e.g.,

This indicates that n calcium molecules from the cytosol bind to the pump when the binding

sites are facing the cytosol, i.e., in the P_{cyt} conformation. Next, the conformation changes so that binding sites are facing the extracellular space or lumen of the organelle (P_{ec} conformation), and then the calcium molecules dissociate to the extracellular space or internal organelles. This reaction scheme can be modeled as explained for enzyme reactions. Reaction Scheme 1 already simplifies the enzyme reaction which involves ATP hydrolysis and thus involves additional states. A 12 state model includes more detail and varying degrees of cooperativity among calcium ions (Tran et al. 2009). Alternatively, reaction scheme can be simplified further by assuming that the conformational changes are instantaneous:

This enzyme reaction can be modeled either stochastically or deterministically as a system of three elementary reactions, but usually they are simplified further using the Michaelis-Menton formulation, which gives calcium flux, Φ :

$$\Phi = \frac{V_{\max}[Ca^{++}]^n}{[Ca^{++}]^n + K_D^n} \quad (3)$$

For the smooth endoplasmic reticulum calcium ATPase (SERCA) pump, K_D is 0.1 μM (Li and Rinzel 1994), and $n = 2$. For the plasma membrane calcium ATPase (PMCA) pump, K_D is 1.0 μM (Enyedi et al. 1994), and $n = 1$. There is some evidence that the pumps can be modified by calcium. For both pumps, $V_{\max}$ is typically adjusted to effect and is proportional to membrane surface area.

This formulation results in a basal calcium concentration of 0, thus a compensatory leak back into the cytosol is typically included:

$$\Phi = \frac{V_{\max}[Ca^{++}]^n}{[Ca^{++}]^n + K_D^n} - J_L([Ca_{ec}^{++}] - [Ca^{++}]) \quad (4)$$

The second term on the left hand side is a compensatory leak; J_L is adjusted such that net

calcium flux from the organelle lumen (or the extracellular space for the PMCA) is zero at the desired basal calcium value. This formulation is widely used, both in models of neurons (e.g., Blackwell 2002; Amini et al. 1999) and cardiac myocytes (e.g., Jafri et al. 1998; Korhonen et al. 2008).

The other pump is the sodium-calcium exchanger (NCX), which depends on both internal and external sodium and calcium concentration. Because this exchanger derives energy from the sodium concentration gradient, it exhibits a dependence on membrane voltage. Several different formulations of this exchanger have been proposed in an attempt to capture all dependencies on ion concentration. One formulation (Gall et al. 1999) calculates dependence on membrane potential from the reversal potential for calcium and sodium and also has an additional

term describing the sigmoid dependence on internal calcium concentration:

$$\Phi_{NCX} = \frac{V_{NCX}}{F} \cdot \text{area} \cdot \left(\frac{[Ca^{++}]^n}{[Ca^{++}]^n + K_{NCX}} \right) \cdot (V_M - V_{NaCa})$$

$$V_{NaCa} = \frac{R \cdot T}{F} \left(m \ln \frac{[Na^+]_o}{[Na^+]_i} - \ln \frac{[Ca^{2+}]_o}{[Ca^{2+}]_i} \right) \quad (5)$$

The factor of m in the equation for Φ_{NCX} represents a stoichiometry of $m Na^+$ to $1 Ca^{2+}$, which is typically 3 or 4 (Fujioka et al. 2000; Blackwell 2004; Kang and Hilgemann 2004). V_{NCX} is the exchanger capacity, V_M is membrane potential, T is temperature, R is the ideal gas constant, and F is Faraday's constant.

A different formulation was derived to account for the currents observed in bull-frog cardiac atrial cells (Campbell et al. 1988).

$$I_{NCX} = V_{NCX} \frac{([Na^+]_i^3 [Ca^{++}]_o \exp \frac{\gamma(r-2)V_M F}{RT} - [Na^+]_o^3 [Ca^{++}]_i \exp \frac{-(1-\gamma)(r-2)V_M F}{RT})}{1 + d_{NaCa} ([Na^+]_i^3 [Ca^{++}]_o + [Na^+]_o^3 [Ca^{++}]_i)} \quad (6)$$

This formulation has been used in several models (Amini et al. 1999; Rasmusson et al. 1990). Since the driving potential for calcium depends on sodium, these models often include equations for the sodium-potassium exchanger.

Due to the importance of calcium for excitation-contraction coupling, many models of cardiac myocytes have even more elaborate models of the NCX that are based on an influential model (DiFrancesco and Noble 1985):

$$I_{NCX} = V_{NCX} \frac{([Na^+]_i^3 [Ca^{++}]_o \exp \frac{\gamma V_M F}{RT} - [Na^+]_o^3 [Ca^{++}]_i \exp \frac{-(1-\gamma)V_M F}{RT})}{(K_{m,Na}^3 + [Na^+]_o^3) (K_{m,ca} + [Ca^{++}]_o) (1 + K_{sat} \exp \frac{-(1-\gamma)V_M F}{RT})} \quad (7)$$

In addition to dependence on membrane potential and concentration gradients, this equation also has terms representing saturation of the exchanger by external sodium concentration and calcium concentration. This equation has been used in models to show that enhanced activity of the NCX contributes to prolongation of the cardiac AP (Priebe and Beuckelmann 1998), to show that

genetic alterations of NCX can indeed account for alternations in excitation contraction coupling (Korhonen et al. 2008), and to demonstrate how force generation is altered by changes in heart rate (Jafri et al. 1998).

An even more elaborate equation was developed (Weber et al. 2001) to account for allosteric modulation of NCX. That equation also has been

used in several models of cardiac action potentials (Rovetti et al. 2010; Hund and Rudy 2004).

A different approach is to use Markov kinetic models to describe activity of the exchanger (Omelchenko and Hryshko 1996; Haase and Hartung 2009; Kim and Matsuoka 2008). The goal of this approach is to understand state transitions of the molecule and to completely capture effects of voltage and ion concentration on exchanger current for a wide range of conditions.

In summary, the large number of studies and models reflects the importance of control of calcium concentration for cell function.

Calcium Release, Models of

Geneviève Dupont

Theoretical Chronobiology Unit, Université Libre de Bruxelles, Brussels, Belgium

Definition

Intracellular Ca^{2+} levels control nearly all cell functions. To adequately fulfill its physiological

roles, cytosolic Ca^{2+} concentration is thus dynamically regulated by channels mediating Ca^{2+} exchanges with the extracellular medium or with intracellular stores, by proteins acting as Ca^{2+} buffers and by diffusion. In neurons, as in other electrically excitable cells, Ca^{2+} changes are mainly carried by Ca^{2+} entry from the exterior, through voltage-dependent Ca^{2+} channels. These channels are able to generate large increases in cytosolic Ca^{2+} in a few milliseconds. In contrast, in electrically non-excitable cells, the main source for Ca^{2+} is the endoplasmic reticulum (ER). Release of Ca^{2+} from the ER occurs through the inositol 1,4,5-trisphosphate receptor (InsP_3R) or through the ryanodine receptor (RyR) in response to a hormonal stimulation (Fig. 1).

However, also in neurons, release of ER Ca^{2+} can be triggered during an action potential and thereby modulate Ca^{2+} -activated plasma membrane channels and affect neuronal excitability. Thus, Ca^{2+} exchanges between intracellular organelles and the cytoplasm need to be accurately modelled when describing the signaling activity of neurons. Of particular importance is the fact that Ca^{2+} can be released from the ER in a regenerative manner, through the so-called Ca^{2+} -induced Ca^{2+} release regulation. This autocatalytic regulation, mediated by either the InsP_3R or the RyR , allows for an excitable process additional to plasma membrane electrical activity. Other factors control cytoplasmic Ca^{2+} changes in a way that is

independent from the electrical properties of the plasma membrane, such as buffers, ATP-driven Ca^{2+} pumps, Ca^{2+} exchangers, InsP_3 metabolism, mitochondria, or store-operated Ca^{2+} entry (Keener and Sneyd 2009). Factors that control Ca^{2+} dynamics in a voltage-independent way are reviewed here below, both from a biological and a modelling point of view.

Detailed Description

Calcium Channels

At rest, Ca^{2+} concentration is low (30–100 nM) in the cytoplasm and mitochondria and high (0.5–1 mM) in the extracellular medium and ER. These gradients allow for a rapid increase in cytosolic Ca^{2+} following the opening of specific Ca^{2+} channels when required for the signaling function of the cell. On the other hand, maintenance of these gradients occurs through active, ATP-dependent pumping.

InsP3 Receptor

The InsP_3 receptor is a tetrameric protein located in the membrane of the ER, although the presence of this receptor has also been reported in the perinuclear or plasma membrane (Parys and De Smedt 2012). This receptor is a Ca^{2+} channel that, when opened, lets Ca^{2+} flow along its gradient. Its Ca^{2+} -releasing activity is not only regulated by

Calcium Release, Models of,

Fig. 1 Schematic representation of the main processes regulating cytosolic Ca^{2+} concentration in electrically non-excitable cells

InsP3 but also by the Ca^{2+} concentration at the cytoplasmic terminal: Ca^{2+} concentrations up to ~300 nM tend to open the channel, while higher concentrations inhibit Ca^{2+} release, albeit on a slower time scale. The activation, acting as an autocatalytic regulation through which Ca^{2+} activates its own release in the cytoplasm, plays a major role in the occurrence of the well-known Ca^{2+} oscillations observed in most non-excitable cell types (Berridge 2012).

Deterministic Model

Models can describe sequential activation and inhibition by assuming that the InsP3 receptor possesses 3 types of binding sites: one for InsP3, one for Ca^{2+} with an activatory effect, and one for Ca^{2+} with an inhibitory effect, characterized by a lower affinity for Ca^{2+} . These detailed models for the receptor (see Thul et al. 2008, for review) can accurately describe the properties of the channel and are easily implemented to perform stochastic simulations (Falcke 2004). When the cellular behavior is the subject of interest, such models can be simplified on the basis of the different time scales of the activatory and inhibitory processes (Dupont et al. 2011). The evolution of the fraction of inhibited channels can be described by a unique differential equation:

$$\frac{dR_i}{dt} = k_+ C^{ni} \frac{1 - R_i}{1 + \left(\frac{C}{k_{act}}\right)^{na}} - k_- R_i$$

where k_+ and k_- are the kinetic constants of Ca^{2+} association to and dissociation from the inhibitory Ca^{2+} binding site of the receptor, C represents the concentration of cytosolic Ca^{2+} , and K_{act} is the dissociation constant of Ca^{2+} binding to the activating Ca^{2+} binding site of the InsP3 receptor. Thus, Ca^{2+} can be released from the ER through the InsP3 receptor when it is active (i.e., open); the fraction of open channel is related to the fraction of inhibited receptor by the following algebraic equation:

$$IR_a = (1 - R_i) \frac{C^{na}}{(K_{act})^{na} + C^{na}} \frac{IP^3}{(K_{IP})^3 + IP^3}$$

Even at basal InsP3 concentration, the InsP3R/ Ca^{2+} channel can release Ca^{2+} through its

autocatalytic activation and amplify Ca^{2+} entry through voltage-gated Ca^{2+} channels.

A more accurate description of InsP3-induced Ca^{2+} fluxes can be obtained when taking into account the existence of the isoforms of this receptor/channel. Three isoforms have been identified (InsP3R1, InsP3R2, and InsP3R3), and their levels of expression are largely tissue specific. Experiments where the levels of expression of these isoforms have been modified (overexpress or knockdown) clearly indicate that their proportions significantly affect the time course of cytosolic Ca^{2+} concentration (Hattori et al. 2004). Although all the InsP3 receptor subtypes display similar permeation properties, they differ significantly in their regulatory properties due to different interactions with accessory proteins, various modes of regulation by ATP, or phosphorylation (Parys and De Smedt 2012). The characteristics of one specific receptor subtype can be considered in a model by assigning the appropriate values to the dissociation constants for IP3 binding, Ca^{2+} binding to the activatory site, and Ca^{2+} binding to the inhibitory site. Although still controversial, putative values are summarized in the table below:

	Type 1(μM)	Type 2(μM)	Type 3(μM)
K_{IP}	0.50	0.20	4.00
K_{act}	0.50	0.50	0.50
K_{inh}	0.50	0.25	1.15

In this table, the dissociation constant for Ca^{2+} on the inhibitory site corresponds to

$$K_{inh} = \left(\frac{k_-}{k_+}\right)^{1/ni}$$

As another difference, the evolution equation for the fraction of inhibited receptor has to be slightly modified to reproduce the behavior of the InsP3R1: it is assumed that InsP3 inhibits Ca^{2+} binding to the inhibitory site, which is necessary to account for the observation that for type 1 receptors, inhibition occurs for higher concentrations of cytosolic Ca^{2+} when the concentration

of InsP3 increases (Dupont and Combettes 2006). The appropriate equation is then

$$\frac{dR_i}{dt} = k_+ C^{ni} \frac{1 - R_i}{1 + \left(\frac{C}{k_{oct}}\right)^{na}} \frac{(K_{IP})^3}{(K_{IP})^3 + IP^3} - k_- R_i$$

Stochastic Model Accounting for Mode Changes
Deterministic models do a very good job in simulating global Ca^{2+} changes and in reproducing most characteristics of signal-induced Ca^{2+} oscillations. However, in order to understand measurements of time-dependent single-channel currents through an InsP3R (Ionescu et al. 2007; Mak et al. 2007), stochastic models describing the transitions between many channel states need to be considered.

In particular, recent experiments revealed that the InsP3R exhibits mode changes: the average open probability indeed jumps between two levels even when ligand (Ca^{2+} , InsP3, or ATP) concentrations are kept constant. These modes are referred to as drive (highly active) and park (inactive) modes by Siekmann et al. (2012). In each of these modes, the receptor can exist in different open or closed states. By comparing fits of Markov models with different numbers of states and different topologies, it was found that the drive mode is best represented by a model with one open and three closed states, while the best model for the park mode only has one open and one closed state (Fig. 2).

Inside each mode, rate constants are ligand independent. Some of these constants are different for the type I and the type II InsP3R. Only the transition rates between both modes, q_{24} and q_{42} , are fitted by different values depending on the concentrations of Ca^{2+} , IP3, and ATP. These values are given for a large set of conditions in Siekmann et al. (2012). Interestingly, the park and drive times depend only on the rates exiting the modes:

$$t_{park} = \left(1 + \frac{q_{45}}{q_{54}}\right) \frac{1}{q_{42}}$$

which can be approximated by $\frac{1}{q_{42}}$ since the ratio $\frac{q_{45}}{q_{54}}$ is low for both types I and II InsP3R.

Calcium Release, Models of, Fig. 2 Drive and Park Markov model for the InsP3R developed by Siekmann et al. (2012)

$$t_{drive} = \left(1 + \frac{q_{21}}{q_{12}} + \frac{q_{23}}{q_{32}} + \frac{q_{36}}{q_{62}}\right) \frac{1}{q_{24}}$$

An important point to remember at this point is that in such type of models, the channel states and connections between them are not related to any underlying reaction scheme. Rather, they represent the most complex model that can be built unambiguously from statistical analysis of single-channel data.

Ryanodine Receptor

Deterministic Model

The ryanodine receptor (RyR) much resembles the InsP3 receptor. It is expressed in all excitable cells. It is responsible for excitation–contraction coupling in muscle cells. The main activator is Ca^{2+} itself, and, as for the InsP3 receptor, excess Ca^{2+} has an inhibitory effect on the RyR, although

the level of Ca^{2+} required for inhibition much depends on the receptor subtype. Other factors that modulate the activity of the RyR are caffeine, ryanodine, and the second messenger cyclic ADP ribose, which may be the endogenous activator of the channel, in the same way as IP3 for the IP3 receptor.

The RyR can be modelled the same way as the InsP3 receptor, although simpler kinetic expressions are also adequate. Modelling studies indeed suggest that inactivation does not play a significant role for RyR-mediated Ca^{2+} release. Indeed, describing this flux by a very simple Hill-type expression, the following sigmoidal function of cytosolic Ca^{2+}

$$V_{\text{RyR}} = \left(k_1 + k_2 \frac{C^3}{(K_o)^3 + C^3} \right) \cdot (C_{\text{ER}} - C)$$

gives excellent agreement with observations in bullfrog sympathetic neurons (Friel 1995). However, simulations of the RyR should take into account the prominent opposition of RyR with plasma membrane Ca^{2+} channels, and more especially L-type Ca^{2+} channels, as geometry is crucial for the Ca^{2+} dynamics (Thul et al. 2012).

Stochastic Model Including Regulation by Ca^{2+} in the ER

A striking property of RyRs is that their activity spontaneously terminates after a few tens of milliseconds. This strongly suggests the existence of an inactivated state. Experimental evidences also show that high levels of Ca^{2+} in the ER increase the open probability of the RyR (Shannon and Bers 2000). A plausible molecular mechanism could involve an interaction between calsequestrin, a widespread ER Ca^{2+} buffer, and the RyR (Györke and Terentyev 2008).

This dual regulation of the RyR by cytosolic and by Ca^{2+} /calsequestrin is taken into account in the model of Restrepo et al. (2008) that assumes the existence of 2 open (O) and 2 closed (C) states (Fig. 3):

Transition from C1 to O1 and from C2 to O2 (Fig. 3) is activated by cytosolic Ca^{2+} . Thus,

$$k_{12} = K_u C^2$$

Calcium Release, Models of, Fig. 3 Model for the RyR and its regulation by calsequestrin developed by Restrepo et al. (2008)

and $k_{43} = K_b C^2$. Calsequestrin regulates the passage from C1 to C2 and from O1 to O2. In fact, only the calsequestrin monomers interact with RyR. Calsequestrin dimerization is favored by high ER Ca^{2+} . Thus, C2 and O2 states are predominant when ER Ca^{2+} is low. Assuming a fast equilibrium between calsequestrin monomers and dimers, Restrepo et al. (2008) have derived an algebraic equation for transition rates:

$$k_{23} = k_{14} = M(C_{\text{ER}})t_b^{-1}$$

where M is an increasing function of C_{ER} .

Other rates are constant. Importantly, $k_{12} > k_{43}$, which means that unbinding of calsequestrin induced by dimer formation at high ER Ca^{2+} leads to an increase in the RyR open probability, as observed experimentally.

Influx

In non-excitable cells, influx of Ca^{2+} is thought to occur through two possible mechanisms, depending on the filling state of the endoplasmic reticulum. Such an influx is thus said to occur through “store-operated Ca^{2+} channels (SOCs).” When the ER is only slightly depleted, the rate of influx is small and proportional to the level of agonist stimulation through a mechanism that may involve arachidonic acid (Shuttleworth 2009). Arachidonic acid is produced by diacylglycerol, a membrane compound that is produced by the same reaction as InsP3. Thus,

this stimulated influx is modelled in the simplest possible way by assuming that the rate of Ca^{2+} entry increases linearly with the level of cell stimulation (Keener and Sneyd 2009).

In most situations, the major molecular components of SOC_s are STIM and Orai. STIM resides in the ER membrane, not far from the plasma membrane where Orai channels are expressed. STIM is able to sense the filling state of the ER (through an EF-hand motif in its N-terminus). Upon Ca^{2+} dissociation, it changes its conformation, which allows self-association of STIM molecules. When aggregated, STIM molecules interact with Orai at plasma membrane junctions. Orai then allows the entry of Ca^{2+} in the cytosol.

A simple model for Ca^{2+} entry based on the STIM–Orai interaction has been proposed by Liu et al. (2010). Ca^{2+} flux through SOC channels is given by

$$V_{IN} = V_{SOC}[SO] \frac{C_{ex}}{K_{ex} + C_{ex}}$$

where $[SO]$ represents the fraction of open SOC_s and V_{SOC} the maximal rate of Ca^{2+} entry of extracellular Ca^{2+} (C_{ex}) through SOC channels. Open SOC_s correspond to STIM–Orai complexes. Thus, $[SO]$ must be computed as the ratio between the concentration of STIM–Orai complexes and the total concentration of Orai. Its time evolution is simply given by the balance between STIM–Orai binding and unbinding, i.e.,

$$\frac{d[SO]}{dt} = f_0(1 - [SO])[STIM] - b_0[SO]$$

where $[STIM]$ represents the concentration of ER Ca^{2+} -free STIM. Thus,

$$\begin{aligned} \frac{d[STIM]}{dt} = & -f_S[STIM](C_{ER})^{ns} \\ & + b_S([STIM]_{tot} - [STIM]) \end{aligned}$$

When solved at steady state, this simple model gives an excellent agreement with the experimental data about store-operated Ca^{2+} entry in human Jurkat T cells (Luik et al. 2008).

Inositol 1,4,5-Trisphosphate Metabolism

Inositol 1,4,5-trisphosphate metabolism is overlooked in most models for intracellular Ca^{2+} dynamics, although it is well known that the level of this messenger has a profound influence on the level of cytosolic Ca^{2+} . It makes no doubt that variations in the concentration of InsP3 will modify the Ca^{2+} flux of Ca^{2+} from the ER through the InsP3 receptor.

InsP3 originates from the receptor-activated hydrolysis of phosphoinositides through well-characterized signaling cascades. The ultimate enzyme of this cascade is membrane-bound phospholipase C. This enzyme possesses several isoforms (β , γ , δ , ϵ , and ζ) differing by the signaling pathway in which they are involved and by their Ca^{2+} sensitivity. PLC β is activated by protein G-coupled receptors, PLC γ by tyrosine kinases, PLC δ by PIP2 and Ca^{2+} , PLC ϵ by Ras, and PLC ζ by Ca^{2+} . Concerning its degradation, InsP3 can be either dephosphorylated by a 5-phosphatase into IP2 or phosphorylated by a 3-kinase into InsP4. The 3-kinase is stimulated by an increase in Ca^{2+} as binding of Ca^{2+} and calmodulin enhances its activity. The stimulation factor varies from 2 to 10 depending on the isoform (Dupont and Erneux 1997). Thus the InsP3-induced Ca^{2+} release leads to a decrease in InsP3 concentration. Another level of complexity comes from the fact that the product of InsP3 phosphorylation by 3-kinase, InsP4, is a competitive inhibitor of the other InsP3-metabolizing enzyme, the 5-phosphatase (Fig. 4).

Because of this network of intertwined regulations, it is difficult to apprehend the interplay between Ca^{2+} and InsP3 concentrations in an intuitive manner. Models taking these regulations into account have proven useful to understand experimental results and make theoretical predictions (Dupont and Erneux 1997; Dupont et al. 2003). Using enzyme kinetics, the evolution of the concentrations of InsP3 and InsP4 can be described as

$$\begin{aligned} \frac{dIP_3}{dt} = & \gamma \cdot V_{PLC} - V_k \frac{IP_3}{K_k + IP_3} \frac{C^4}{(K_o)^4 + C^4} \\ & - V_{P1} \frac{IP_3}{K_{P1} \left(1 + \frac{IP_4}{K_{\phi 2}}\right) + IP_3} \end{aligned}$$

Calcium Release, Models of, Fig. 4

Inositol 1,4,5-Trisphosphate (Ins 1,4,5-P₃) metabolism

$$\frac{dIP_4}{dt} = V_k \frac{IP_3}{K_k + IP_3} \frac{C^4}{(K_o)^4 + C^4} - V_{P2} \frac{IP_4}{K_{P2} \left(1 + \frac{IP_3}{k_{\phi 1}}\right) + IP_4} - k \cdot IP_4$$

The level of Ca²⁺ in the mitochondria thus results from the balance between entry through the uniporter and efflux via the Na⁺-Ca²⁺ exchanger and possibly the permeability transition pore:

$$\frac{dC_m}{dt} = -J_{Na,ex} + J_{uni} + J_{PTP}$$

Mitochondria

Mitochondria also affect cytoplasmic Ca²⁺ signals. They can both buffer cytosolic Ca²⁺ changes and release Ca²⁺. At rest, intramitochondrial and cytosolic Ca²⁺ concentration are similar, of the order of 100 nM. Ca²⁺ entry in the mitochondria occurs through a multistep mechanism. By extruding protons out of the mitochondria, the respiratory chain creates a large inside-negative potential difference across the inner mitochondrial membrane. This ΔΨ_m, which is harnessed by the ATP synthase in the production of ATP, allows a uniporter to transport Ca²⁺ inside the mitochondria when cytosolic Ca²⁺ locally reaches high concentrations, which arises in the close vicinity of ER Ca²⁺ release sites. Ca²⁺ entry then depolarizes the mitochondria, thus reducing its own driving force. When cytosolic Ca²⁺ returns to its basal value, extrusion of Ca²⁺ out of the mitochondria occurs mainly through the rather slow Na⁺-Ca²⁺ exchanger (Santo-Domingo and Demaurex 2010; Rizzuto et al. 2012). In addition to the uniporter/exchanger pathway for Ca²⁺ cycling between the cytosol and the mitochondria, an important increase in matrix Ca²⁺ can also lead to opening of the permeability transition pore (PTP), a voltage-dependent, high-conductance channel behaving as a large pore allowing solutes with a molecular weight less than about 1,500 kDa to equilibrate across the inner membrane.

All fluxes depend on cytosolic Ca²⁺, mitochondrial Ca²⁺, and mitochondrial potential in a complex manner. Detailed, accurate kinetic expressions can be found in the literature (Oster et al. 2011).

Calcium Waves, Models of

M. Saleet Jafri and Aman Ullah

School of Systems Biology and Krasnow Institute for Advanced Studies, George Mason University, Fairfax, VA, USA

Definition

A calcium wave is a transient rise in cytosolic calcium concentration that propagates spatially within the cell. It has the property that it is regenerative and is followed by a refractory period. It is believed that the wave carries a signal from one part of the cell to another.

Detailed Description

Calcium ions play an important role in a variety of cellular functions that impact nearly all aspects of cellular life. In fact, the calcium signal is one of the most versatile and universal signaling agents of the human body that controls almost everything we do – Ca^{2+} ions contribute to egg activation upon fertilization, muscle contraction, enzyme secretion, neurotransmitter release, how our brains process information and store memories, wound healing, and apoptosis. Calcium ions play such an important role in so many biological processes that it has been branded as the “life and death signal” (Berridge et al. 1998).

At rest, intracellular calcium concentration remains low, about 0.1 μM . Transient increases of intracellular Ca^{2+} concentration influence different cellular processes across a variety of different cells. This transient rise can peak at 0.5–3.0 μM depending upon the cell type and signal. The change in Ca^{2+} concentration transmits information through an organized set of spatiotemporal changes (Adkins and Taylor 1999). When considering the inositol 1,4,5-trisphosphate (IP_3) receptor channel that is found on the endoplasmic reticulum, release occurs as localized

blips, puffs, transients, oscillations, and waves (Fig. 1). When considering the ryanodine receptor (RyR) that is found in the sarcoplasmic reticulum, the internal calcium store in muscle, release occurs in the form of quarks (a fundamental opening event) and calcium sparks which are the elementary unit of calcium release which sum up to the calcium transient. The calcium transient can propagate to carry a signal from one part of the cell to another in a calcium wave.

Basic Mechanism of Ca^{2+} Signaling

In the cell cytosol, Ca^{2+} can enter from two sources: (1) from extracellular sources through a variety of plasmalemmal Ca^{2+} channels such as voltage-operated channels (VOCs), receptor-operated channels (ROCs), or store-operated channels (SOCs) or (2) from intracellular Ca^{2+} stores such as the endoplasmic reticulum (ER) and sarcoplasmic reticulum (SR). The endoplasmic reticulum (ER) comprises up to 20 % of the cell; it is the major Ca^{2+} storage organelle in many cell types (Foskett et al. 2007). The extracellular calcium concentration is in the mM range,

whereas the internal concentration in ER is of the order of a few hundred μM and may reach up to mM (Falcke 2004). This provides a large driving force for calcium entry into the cytosol which is much lower. This low concentration of Ca^{2+} is maintained by pumps and other Ca^{2+} transporters located on the ER membrane and plasma membrane (Foskett et al. 2007) as well as intracellular calcium-binding proteins which serve as Ca^{2+} buffers. Hence, a finely tuned mechanism regulates cytosolic calcium.

Mechanisms of Calcium Waves

The specific mechanism of calcium waves can vary depending upon cell type and condition. Mathematically they all have some common features. First, the system must be excitable which means that an increase in calcium above a threshold will trigger additional calcium release. This requires positive feedback of calcium release (such as calcium-induced calcium release) that is possible with systems that contain the IP_3 receptor or the RyR. These can be described as components of a system of coupled differential equations

Calcium Waves,

Models of,

Fig. 1 Calcium blips (or quarks in the case of RyR clusters) are considered to be openings of one or a few IP_3 receptor channels (*top*). Calcium puffs (or sparks in the case of RyR clusters) reflect the opening of a cluster of IP_3 receptor channels (*middle*). When calcium release propagates from one cluster to another, a calcium wave results (*bottom*)

giving the ability to analyze the mechanism of calcium waves. Mathematically a system of differential equations can be studied two variables at a time using a phase plane diagram that explores the values of the derivatives at different values of the variables. The phase plane considers the nullclines (the curves where each derivative is zero), and the values of the derivatives at other points (vector field) define the trajectories of possible solutions. The system can be characterized by an n-shaped nullcline and a second nullcline that is relatively straight that crosses the other at a stable steady state (Fig. 2a). A steady state is the point where the derivatives are all equal to zero. The dashed portion of the n-shaped nullcline is the unstable portion, and the solid portions are the stable portions. A trajectory will move toward the stable portions of the nullcline and away from the unstable portion. At rest, the system will be at its stable steady state shown by the solid black circle. If the perturbation is small and does not cross the dashed portion, the trajectory will return to the steady state. A sufficient perturbation (green arrow) will move the trajectory past the unstable portion of the n-shaped nullcline. The trajectory will then proceed to the right to the stable part of the nullcline (red arrow). The trajectory will then track along the n-shaped nullcline (thick red arrow on right) until it falls off the nullcline and moves left until it finds the other stable part of the n-shaped nullcline (left pointing red arrow). The trajectory will then follow the nullcline back to the steady state (thick red arrow on left). Detail of this mechanism can be found in the model developed by Sneyd and coworkers (Girard et al. 1992). If the “straight” nullcline is shifted so that it crosses the unstable portion of the n-shaped nullcline, oscillations occur (Fig. 2b). Any small perturbation off the unstable steady state (solid black circle) will move to the stable portion of the n-shaped nullcline, and the red trajectory will be followed in an oscillatory fashion, unable to return to the stable point. In models of agonist-induced calcium wave and oscillations, changing the IP_3 concentration would shift the “straight” nullcline. Hence for a range of values of IP_3 (when the “straight nullcline crosses the unstable portion of the n-nullcline (dashed)), oscillations will occur.

Calcium Waves, Models of, Fig. 2 The dynamics of the system of differential equations can be studied with a phase plane diagram that characterizes the trajectories of solutions for two system variables using the vector field (values of derivatives for different values of the variables). (a) An excitable system has this characteristic n-shaped nullcline crossed by a second “straight nullcline” establishing a stable steady state (black circle) so that sufficient perturbations from the stable steady state (green arrow) cross the unstable portion of the n-shaped nullcline. The trajectory then follows the red arrows generating a transient rise in the independent variable of the plot. (b) When the nullclines cross, yielding an unstable steady state (black circle), perturbations off the steady state result in an oscillatory trajectory

Classification of calcium waves into five categories can be accomplished by the mechanism giving rise to the waves: (1) membrane depolarization-triggered calcium waves, (2) agonist-induced calcium waves, (3) fire-diffuse-fire calcium waves, (4) calcium phase waves, and (5) kinematic calcium waves. A common feature of these mechanisms is that they all involve calcium release from

the endoplasmic reticulum which is an intracellular calcium store. These calcium waves can be found in single cells as well as multicellular systems.

Membrane Depolarization-Triggered Calcium Waves – In this type of wave, a propagating signal triggers release of calcium from internal stores resulting in calcium waves. For example, membrane depolarization, as seen during an action potential, results in the opening of voltage-gated calcium channels. The wave of depolarization triggers calcium release from the intracellular stores in two ways. In the case of ryanodine receptor type 1 (RyR1) in skeletal muscle, the conformational change in the voltage-gated L-type calcium channel during opening triggers a conformational change in the adjacent RyR1 causing calcium release from the sarcoplasmic reticulum. On the other hand, in

cardiac myocytes which contain ryanodine receptor type 2 (RyR2), the calcium entry through these plasmalemmal calcium channels can trigger calcium release from the internal stores through a calcium-induced calcium-release mechanism. These waves are quite fast as in an action potentials the depolarization propagates very rapidly across the plasmalemma. In networks of neurons, the rapid spread of depolarization between neurons or astrocytes can trigger a wave of calcium elevation in these cells. In other cells, this can involve either ryanodine receptors, IP₃ receptors, or both.

Agonist-Triggered Calcium Waves – A wave of IP₃ has been observed to trigger a wave of calcium release from the endoplasmic reticulum in oocytes during fertilization. This occurs as IP₃ binds to the IP₃ receptor in the ER-releasing calcium (Fig. 3a).

Calcium Waves, Models of,

Fig. 3 Schematic diagram of mechanisms of calcium waves. (a) Agonist-triggered calcium wave. (b) Fire-diffuse-fire calcium wave

The calcium activates IP_3 production allowing the wave of IP_3 to propagate (Fall et al. 2004). Another example is the calcium waves observed in airway epithelium cells where calcium waves depend upon IP_3 diffusion (Sneyd et al. 1995). The speed of these waves is governed by the propagation speed of the wave of IP_3 which is controlled by the IP_3 diffusion rate and its dynamics.

Fire-Diffuse-Fire Calcium Waves – In this type of calcium wave (Fig. 3b), calcium released from the endoplasmic reticulum through channels, such as the IP_3 receptor or ryanodine receptor, diffuses to adjacent channels and triggers release from these sites through calcium-induced calcium release (Atri et al. 1993; Jafri and Keizer 1995). The wave speed (c) of this type of waves is proportional to the square root of the effective

diffusion constant, D_{eff} , for calcium divided by a characteristic time, T_1 :

$$\text{i.e., } c^2 = D_{\text{eff}}/T_1.$$

Calcium Phase Waves – Phase waves result from a series of spatially adjacent oscillators in which there is a slight phase delay between oscillators as one moves down the chain of oscillators. For example, during receptor stimulation by an agonist, IP_3 is produced which induces calcium oscillations. The initial gradient of IP_3 can initiate calcium oscillations sequentially from sites moving down the initial gradient. As these sites fire in sequence, it appears that a wave of calcium actually propagates even though there is no diffusion of calcium (and no net movement of calcium). Instead, there are localized cycles of uptake and release that give the appearance of a wave (Fig. 4).

Calcium Waves, Models of, Fig. 4 The spatial length between two waves is the wavelength (λ), and the time between two successive transients is the period between oscillations (τ). The phase of the oscillation for the spatial point shown by the red dashed line is shown by the clocks on the right. When the arrow is pointing up, a calcium transient occurs as a cycle of local calcium uptake and

release. As the phase progresses, the waves propagate to the right as shown by the purple arrows even though there is no calcium diffusion. As the phase advances through one period (from top to bottom on right), the wave advances to the right by one wavelength (left). Hence the wave speed is the ratio of wavelength do period, i.e., $c = \lambda/\tau$

For these waves, the wave speed is equal to the ratio of the wavelength to the period of oscillation (Jafri and Keizer 1994; Jafri and Keizer 1995).

Kinematic Calcium Waves – Kinematic waves are related to phase waves but actually have weak diffusion of calcium. Murray provides a mathematical description of kinematic waves (Murray 1993). As calcium is highly buffered, calcium diffusion in cells is slow and can be considered weak. Hence, with oscillatory calcium dynamics, kinematic waves are observed. Waves propagate as a result of local cycles of uptake and release with little diffusion. This was first suggested for calcium waves by Jafri and Keizer (Jafri and Keizer 1994; Jafri and Keizer 1995, 1997). This type of wave has been observed experimentally in astrocytes by Russell and coworkers and has been described by a model (Roth et al. 1995). As with phase waves, the wave speed is equal to the ratio of the wavelength to the period of oscillation (Fig. 5). Experimental data from oocytes under certain conditions also support this relation (Lechleiter et al. 1998).

Calcium Waves, Models of, Fig. 5 The wave speed is equal to the oscillation wavelength divided by the oscillation period ($c = \lambda/\tau$). Changing the level of IP_3 alters the oscillation frequency ($1/\tau$) and alters the slope of the line. Shown are data points from simulations. Normal diffusion with $[IP_3] = 0.52 \mu M$ (red squares). No diffusion with $[IP_3] = 0.52 \mu M$ (blue diamonds). Normal diffusion with $[IP_3] = 0.26 \mu M$ (purple circles). No diffusion with $[IP_3] = 0.26 \mu M$ (green triangles). Lines represent linear curves fitted for data going through the origin. (The figure is reproduced from data in Jafri and Keizer (1994).)

Example of Deterministic Model for Ca^{2+} Waves

The Jafri-Keizer model provides an example of a computational model for calcium waves that produces fire-diffuse-fire calcium waves, phase waves, and kinematic waves. The model consists of five differential equations for the dynamic variables: cytosolic calcium concentration ($[Ca^{2+}]_{cyt}$), endoplasmic reticulum calcium concentration ($[Ca^{2+}]_{ER}$), cytosolic IP_3 concentration ($[IP_3]$), and the fraction of channels in the open and closed states of the IP_3 receptor (X_{100} and X_{101} , respectively). The dynamics of the cytosolic calcium concentration is described by the contributions of diffusion ($J_{diffusion}$), ER calcium leak (J_{leak}),

calcium release from the IP_3 receptor ($J_{release}$), and sequestration back into the ER by the ER calcium pump (J_{pump}). These fluxes are buffered by native and exogenous molecules (fluorescent indicator dyes):

$$\frac{\partial [Ca^{2+}]_{cyt}}{\partial t} = \beta_{cyt} [J_{diffusion} + J_{leak} + J_{release} - J_{pump}]. \quad (1)$$

The buffering of calcium (β_{cyt}) is described by the rapid buffering approximation (Wagner and Keizer 1994):

$$\beta_{cyt} = \left\{ 1 + \frac{[B_s]_{cyt} K_s^{cyt}}{(K_s^{cyt} + [Ca^{2+}]_{cyt})^2} + \frac{[B_m]_{cyt} K_m^{cyt}}{(K_m^{cyt} + [Ca^{2+}]_{cyt})^2} + \frac{[B_e]_{cyt} K_e^{cyt}}{(K_s^{cyt} + [Ca^{2+}]_{cyt})^2} \right\}^{-1}, \quad (2)$$

where $[B_i]_{\text{cyt}}$ is the total concentration of cytosolic calcium buffer i and K_i^{cyt} is its disassociation constant for calcium with the subscripts $i = s, m, e$ represent native stationary buffer, native mobile buffer, and exogenous buffers, respectively. The

diffusion of calcium ($J_{\text{diffusion}}$) and the contributions to calcium diffusive flux due to calcium bound to mobile buffers (native, m , and exogenous, e) are described by

$$J_{\text{diffusion}} = (D_{\text{Ca}}^{\text{cyt}} + \gamma_m^{\text{cyt}} D_m^{\text{cyt}} + \gamma_e^{\text{cyt}} D_e^{\text{cyt}}) \nabla^2 [Ca^{2+}]_{\text{cyt}} - 2 \left(\frac{\gamma_m^{\text{cyt}} D_m^{\text{cyt}}}{K_m^{\text{cyt}} + [Ca]_{\text{cyt}}} + \frac{\gamma_e^{\text{cyt}} D_e^{\text{cyt}}}{K_e^{\text{cyt}} + [Ca]_{\text{cyt}}} \right) \nabla [Ca]_{\text{cyt}} \cdot \nabla Ca_{\text{cyt}}, \quad (3)$$

where D_i^{cyt} is the diffusion constant for calcium, native mobile buffer, and exogenous buffers ($i = \text{Ca}, m, e$, respectively) and γ_i^{cyt} is ($i = m, e$, respectively)

$$\gamma_i^{\text{cyt}} = \frac{[B_i]_{\text{cyt}} K_i^{\text{cyt}}}{(K_i^{\text{cyt}} + [Ca]_{\text{cyt}})^2} \quad (4)$$

These equations are also derived from the rapid buffer approximation (Wagner and Keizer 1994).

The release of calcium from the IP_3 receptor is described by

$$J_{\text{release}} = c_1 v_1 X_{110}^3 ([Ca^{2+}]_{\text{ER}} - [Ca^{2+}]_{\text{cyt}}), \quad (5)$$

where c_1 is the ER/cytosol volume ratio and v_1 is the maximal calcium ion flux through the channel.

There is also a passive leak out of the ER given by

$$J_{\text{leak}} = c_1 v_2 ([Ca^{2+}]_{\text{ER}} - [Ca^{2+}]_{\text{cyt}}), \quad (6)$$

with maximal rate v_2 . The pump that sequesters calcium back into the ER is described by

$$J_{\text{pump}} = \frac{v_3 [Ca^{2+}]_{\text{cyt}}^2}{[Ca^{2+}]_{\text{cyt}}^2 + K_3^2}, \quad (7)$$

with v_3 being the maximal pump rate and K_3 the binding constant for calcium.

The balance equation for ER calcium mirrors that of cytosolic calcium except that the transmembrane fluxes have the opposite effect and the buffers and diffusion are those of the ER:

$$\frac{\partial [Ca^{2+}]_{\text{ER}}}{\partial t} = \beta_{\text{ER}} \left[\left(D_{\text{Ca}}^{\text{ER}} + \gamma_m^{\text{ER}} D_m^{\text{ER}} [Ca^{2+}]_{\text{ER}} - 2 \frac{\gamma_m^{\text{ER}} D_m^{\text{ER}}}{K_m^{\text{ER}} + [Ca]_{\text{ER}}} \nabla Ca_{\text{ER}} \nabla Ca_{\text{ER}} - (v_2 + v_1 X_{110}^3) \right) * ([Ca^{2+}]_{\text{ER}} - [Ca^{2+}]_{\text{cyt}}) + \frac{1}{c_1} \frac{v_3 [Ca^{2+}]_{\text{cyt}}^2}{[Ca^{2+}]_{\text{cyt}}^2 + k_3^2} \right], \quad (8)$$

where

$$\beta_{\text{ER}} = \left\{ 1 + \frac{[B_s]_{\text{ER}} K_s^{\text{ER}}}{(K_s^{\text{ER}} + [Ca^{2+}]_{\text{ER}})^2} + \frac{[B_m]_{\text{ER}} K_m^{\text{ER}}}{(K_m^{\text{ER}} + [Ca^{2+}]_{\text{ER}})^2} \right\}^{-1} \quad (9)$$

and

$$\gamma_m^{ER} = \frac{[B_m]_{ER} K_s^{ER}}{(K_m^{ER} + [Ca]_{ER})^2}. \quad (10)$$

The dynamics of IP_3 are described by

$$\begin{aligned} \frac{\partial [IP_3]}{\partial t} &= D_{IP_3} \nabla^2 [IP_3] \\ &+ I_r([IP_3] * -[IP_3]), \end{aligned} \quad (11)$$

where D_{IP_3} is the diffusion constant for IP_3 and I_r is the relaxation rate of IP_3 to its steady-state value $[IP_3]^*$. The state of the IP_3 receptor is given by

$$\begin{aligned} \frac{dX_{100}}{dt} &= -a_2 [Ca^{2+}]_{cyt} X_{100} \\ &- a_5 [Ca^{2+}]_{cyt} X_{100} + b_5 X_{110}, \end{aligned} \quad (12)$$

$$\begin{aligned} \frac{dX_{110}}{dt} &= -a_2 [Ca^{2+}]_{cyt} X_{110} + b_2 c_2 [IP_3] \\ &+ a_5 [Ca^{2+}]_{cyt} X_{100} + b_5 X_{110}, \end{aligned} \quad (13)$$

with the transition rate constants a_i and b_i and the proportionality constant c_2 for X_{111} (the state with IP_3 , activating and inactivating calcium bound) binding to IP_3 . The model for the IP_3 receptor was first described by DeYoung and Keizer as an eight-state system and reduced to a two-state system used here (De Young and Keizer 1992; Keizer and De Young 1994).

To demonstrate the model, a simulated spiral wave based upon this model (Jafri and Keizer 1995) is shown here (Fig. 6).

Example of a Stochastic Model for Ca^{2+} Wave

The physiological events that underlie calcium waves are the stochastic opening and closing of ion channels. Experiments have observed this stochastic behavior as calcium blips, puffs, and waves. Hence to understand the dynamics of these molecular events that underlie calcium waves, stochastic models are needed. As an example, a model of a

Calcium Waves, Models of, Fig. 6 Spiral calcium wave produced by the Jafri and Keizer model for agonist-induced calcium waves in *Xenopus laevis* oocytes (click for movie)

calcium wave in the mature *Xenopus laevis* oocyte is presented (Ullah 2011). For the simulation, each single IP_3 channel was modeled with four equal and independent subunits, where the kinetics of each subunit is determined by the simplified version of Sneyd and Dufour model (Sneyd and Dufour 2002). The channels were clustered into groups of 20 channels. The spatiotemporal Ca^{2+} dynamics are described by the following equation:

$$\frac{dc}{dt} = D_{cyt} \nabla^2 c + J_{cluster} \delta(\vec{x} - \vec{x}_n) - J_{serca} + J_{leak'} \quad (14)$$

$$\begin{aligned} \frac{dc_{ER}}{dt} &= D_{ER} \nabla^2 c_{ER} \\ &+ \gamma (J_{serca} - J_{cluster} \delta(\vec{x} - \vec{x}_n) - J_{leak}), \end{aligned} \quad (15)$$

$$\frac{dp}{dt} = D_p \nabla^2 p + \beta(p^* - p) + J_{stim} + J_{PLC\delta}, \quad (16)$$

where “c” is the cytosolic calcium concentration; c_{ER} denotes the concentration of calcium in the ER; D_{cyt} and D_{ER} are the effective diffusion

Calcium Waves, Models of, Fig. 7 Snapshots of Ca^{2+} wave after injecting an IP_3 stimulus. The wave propagates to the *right*; the calcium released in the cytosol provides positive feedback for the propagation of the Ca^{2+} wave across the cytosol through further activation of IP_3R . IP_3 receptors are modeled with 20 channels per cluster at a distance of $3\ \mu\text{m}$ uniformly distributed throughout the two-

dimension grid. The global Ca^{2+} wave is generated by applying an IP_3 stimulus J_{stim} in Eq. 13, along a line at the *left edge* of the grid. It activates the IP_3 receptors and initiates the Ca^{2+} wave. The IP_3 then diffuses to the cytosol, activates the internal IP_3Rs , opens up the channels, and releases more Ca^{2+} from the internal store ER to generate the self-sustaining wave

coefficients of calcium in the cytosol and in the ER, respectively; and D_p is the diffusion coefficient of IP_3 . The parameter γ denotes the ratio of the cytoplasmic volume to the ER volume and is used to account for different volumes of two compartments. The term J_{cluster} represents the Ca^{2+} of an IP_3 receptor containing a small cluster of channels. The magnitude of this flux depends on both the number of open channels within the cluster and the Ca^{2+} gradient across the ER membrane:

$$J_{\text{cluster}} = N_{\text{open}} \pi r^2 v_{\text{channel}} (c_{\text{ER}} - c), \quad (17)$$

Here r represents the channel cross-sectional radius. N_{open} is the number of open channels, and v_{channel} is the maximum Ca^{2+} flux per channel. N_{open} is obtained from the kinetics of the IP_3 receptors, which are modeled stochastically, i.e., the number of open channels is random, as each channel can open and close stochastically.

The leak term J_{leak} represents the loss of Ca^{2+} through the ER membrane, into the cytosol. Similar to the cluster's flux, the leak flux also depends on a concentration gradient, as well as v_{leak} the maximum leak conductance:

$$J_{\text{leak}} = v_{\text{leak}} (c_{\text{ER}} - c). \quad (18)$$

As cell function is highly dependent on a high Ca^{2+} gradient across the ER membrane, the

cell requires ATP-driven SERCA pumps (sacro-/endoplasmic reticulum Ca^{2+}) to be distributed across the ER membrane. The J_{serca} term in Eq. 11 represents this mechanism and follows a similar form as Eq. 7:

$$J_{\text{serca}} = v_{\text{serca}} \frac{c^2}{(k_{\text{serca}}^2 + c^2)} \quad (19)$$

Phospholipase C (PLC_δ) in the plasma membrane stimulates production of IP_3 upon increasing cytosolic Ca^{2+} levels, i.e.,

$$J_{\text{PLC}_\delta} = V_{\text{PLC}_\delta} \frac{c^2}{(k_{\text{PLC}_\delta} + c^2)}. \quad (20)$$

PLC_δ is an important signaling effector as it increases sensitivity to IP_3 and facilitates an intracellular calcium wave (Fig. 7).

Conclusions

In summary, calcium waves are ubiquitous throughout biological systems. They allow the spatial and temporal control of calcium in different parts of the cell. As calcium waves are complex nonlinear phenomena, mathematical models have played an important role in understanding their dynamics.

BK channels (KCa1.1); SK channels (KCa2.x)

Definition

Calcium-dependent potassium channels are potassium-permeable channels whose gating is regulated by the intracellular calcium concentration. Small-conductance (10–20 pS) calcium-activated (SK) channels are purely gated by calcium, while the opening probability of large-conductance (> 100 pS) calcium-activated (BK) channels is a complex function of both membrane potential and intracellular calcium concentration (Fig. 1). Both SK and BK channels are composed of four subunits. Intermediate-conductance (IK) channels, which are not expressed in neurons, are not considered further here.

Detailed Description

Gating Properties

SK channels activate at relatively low calcium concentrations (100 nM to 1 μM , Fig. 1, left).

Their opening is regulated by the interaction between calcium ions and calcium-binding proteins (calmodulins), which are constitutively associated with each subunit. Main sources of calcium include voltage-dependent calcium (CaV) channels, NMDA receptors, and various types of intracellular stores. The time constant of SK channel activation (5–15 ms) is much faster than the calcium oscillations involved in pacemaking of most neurons. These channels can therefore be considered as rapid “calcium followers.” As a consequence, their intrinsic kinetics is generally modeled as instantaneous.

BK channels are solely active during the repolarizing phase of the action potential, because they need both a rather strong depolarization and a large calcium concentration to activate (Fig. 1, right). In addition, they deactivate very quickly. Therefore, they modulate the action potential duration and are able to generate a fast (few milliseconds) afterhyperpolarization. Because of their large hyperpolarizing effect, they are able to modulate the availability of other voltage-dependent channels. They have no significant

role during most of the interspike interval, contrary to SK channels.

Effect on Intrinsic Neuronal Excitability

In pacemaker neurons, SK channel activation promotes regular interspike intervals (ISIs). In many cases, application of SK blockers has been shown to deregulate firing and/or induce bursting behavior, both in vitro and in vivo (see, e.g., Feng and Jaeger 2008 and Waroux et al. 2005) (Fig. 2). In these neurons, SK channels produce a large afterhyperpolarization (AHP), whose duration varies depending on the kinetics of the calcium oscillations. Because the conductance involved is rather large, the neuron is very insensitive to incoming noise during this event, preventing the generation of premature action potentials.

The importance of the regularity promoting effect of SK channels has been emphasized in the case of cerebellar Purkinje neurons. Indeed, a loss of precision of pacemaking in these cells is

SK Channels

voltage-dependent activation of BK channels (Modified from Blatz and Magleby 1986)

Calcium-Dependent Potassium Channels, Fig. 2 Effect of the SK channel blocker apamin on intrinsic dopamine neuron excitability (intracellular recording in a rat brain slice by J. Scuvée-Moreau)

observed in a model of a disease called episodic ataxia type 2 (Alviña and Khodakhah 2010). In the mouse model of the disease, a loss of function is observed in the CaV channels which activate SK channels of Purkinje neurons. Interestingly, regularizing the firing rate through the use of positive modulators of SK channels produces beneficial effects.

In pyramidal neurons, SK channels have been shown to at least contribute to the medium duration AHP and thereby to underlie the phenomenon known as spike frequency adaptation (Hille 2001). In other types of neurons, it has been shown that SK channels contribute to the termination of bursts, such as in Aplysia R15 neurons (Plant and Kim 1976).

BK channels operate during and immediately after the action potential. They have been shown to control action potential width (Bean 2007) and therefore to promote the ability of high-frequency firing. In particular, they prevent incremental inactivation of voltage-gated sodium channels. This action is also performed by other potassium channels (e.g., Kv3) in some neurons. As pointed out

by Bean, the strong repolarizing effect of BK channels explains the counterintuitive observation of a broadening of action potentials during blockade of some CaV channels. In addition, their progressive inactivation may contribute to frequency-dependent broadening of action potentials.

Effect on Synaptic Transmission

Some studies have found evidence for the presence of some SK channel subtypes in axon terminals, but there is scarce information on their physiological roles at this level.

Postsynaptically, SK channels have been found on the soma and dendrites of many neurons. Three roles have been proposed for them: first, they may be in close contact with NMDA receptors on spines of pyramidal neurons. In this case, they may produce a negative feedback in the sense that their activation by calcium influx through NMDA channels will provide a local hyperpolarizing drive that will inhibit further NMDA

receptor activation. Thus, their activation will decrease the likelihood of NMDA-dependent long-term potentiation (Adelman et al. 2011). Second, SK channels have also been reported to contribute to dendritic integration in pyramidal-type neurons. More precisely, they seem to contribute to the repolarization of plateau potentials induced by glutamate. Third, they have been shown to underlie a slow inhibitory postsynaptic potential following activation of Gq-coupled metabotropic receptors, synthesis of inositol triphosphate, and ensuing release of intracellular calcium.

BK channels are present in presynaptic terminals of several types of neurons. By modulating the action potential width, they may have a major effect on the amount of released neurotransmitter.

Definition

Calmodulin (CaM) is a small (148 amino acid) ubiquitous protein responsible for decoding oscillatory changes in intracellular calcium and transducing the signal to downstream targets. Four separate calcium (Ca^{2+})-binding sites are distributed into two globular domains (the N- and C-lobes) tethered together by a linker whose structural flexibility is essential for interactions with its multiple target proteins. So, despite its small size, there are significant complexities in building quantitative mathematical models to accommodate the multitude of different structural (liganded) states that ultimately dictate CaM's functions. Detailed molecular modeling is beginning to advance our understanding for how this single protein can interact with several unique target proteins in both Ca^{2+} -bound (holoCaM) and Ca^{2+} -free (apoCaM) states.

Detailed Description

CaM is typically described as a dumbbell-shaped protein with two globular domains connected through a central helix (Crivici and Ikura 1995). Each globular domain contains two EF hand Ca^{2+} -binding sites, and the affinity of each site for Ca^{2+} and their binding kinetics is fairly well characterized (Linse et al. 1991; Bayley et al. 1996; Gaertner et al. 2004; Putkey et al. 2008; Faas et al. 2011). The N-domain sites are labeled 1 and 2 and those in the C-domain are labeled 3 and 4 (Fig. 1), and the experimentally determined macroscopic binding constants can be found in Table 1. Ca^{2+} binding between site

Calmodulin, Models of, Fig. 1 Structures of CaM in the absence (a and c) and presence (b and d) of Ca²⁺. The N- and C-terminus of CaM are colored in yellow and red, respectively, and Ca²⁺ ions are represented by green spheres. Ribbon representations of apoCaM and holoCaM are shown in (a) and (b) and the C_α side-chain representations of the same structures are shown in (c) and (d).

Calmodulin, Models of, Table 1 Ca²⁺binding to CaM

Site	K _d (μM)	K _{off} (s ⁻¹)	K _{on} (μM ⁻¹ s ⁻¹)
1	40	20,000	500
2	2.5	3000	1200
3	12.6	5100	408
4	0.25	9.1	36.4

1 and site 2 and between site 3 and site 4 exhibits cooperativity. Under steady-state conditions, the C-lobe has a ~ 5- to six-fold greater average binding affinity for Ca²⁺ (~1.7 μM) than the N-lobe (~10 μM), indicating that the C-lobe is preferentially occupied under steady-state conditions.

However, since cellular Ca²⁺ levels are constantly fluctuating and under these rapidly varying Ca²⁺ conditions, the kinetics of association and dissociation dictate the probability of N-lobe or C-lobe saturation. The N-lobe binds Ca²⁺ quickly and releases it quickly, while the C-lobe binds and releases Ca²⁺ more slowly. In this way, the N-lobe has the capacity to respond in a switch-like manner to brief Ca²⁺ transients, while the C-lobe kinetics lead to slower activation and longer duration occupancy, loosely analogous to a capacitor. As a consequence, Ca²⁺ binding to the C-lobe of CaM is the rate-limiting step for full occupancy when starting from the apoCaM state. From the intracellular perspective, both the level of resting Ca²⁺ and the shape, amplitude, and frequency of Ca²⁺ oscillations will influence the overall Ca²⁺ occupancy of the different lobes of CaM. Different modeling strategies have been developed to address the complexities of the four separate Ca²⁺-binding sites on CaM (Holmes 2000; Keller et al. 2008; Saucerman and Bers 2008; Stefan et al. 2008; Kubota and Waxham 2010; Faas et al. 2011). Minimally these models incorporate the different K_d and on and off rates for Ca²⁺ binding to the N- and C-lobes of CaM. Coupling factors have been incorporated to accommodate the known cooperativity of Ca²⁺ binding into some models, while others employed the strategy to model each site within each domain independently with a specific on and off rate for Ca²⁺ binding.

In addition to Ca²⁺ binding, CaM can interact with hundreds of target proteins to regulate numerous biochemical, metabolic, and cellular processes (Yamniuk and Vogel 2004; Choi and Husain 2006). Some of these target proteins interact preferentially with apoCaM, while others prefer holoCaM. In both cases, the mutual interactions of specific amino acid residues in CaM and the target molecule dictate target selectivity. From the many CaM/target protein structures available, a few generalizations about binding can be made. The highly malleable structure of CaM is critical, where a helical linker connects the two lobes with notable structural flexibility (Crivici and Ikura 1995; Hoeflich and Ikura 2002; Bhattacharya et al. 2004; Slaughter et al. 2005; Homouz et al. 2009; Price et al. 2010).

Unwinding of the central helix permits the N- and C-lobes to adjust their orientation and relative distance to each other to accommodate unique structural features in the target molecules.

Computer simulations allow the investigation of CaM dynamics involving inter- and intra-domain movement in solution that is a prerequisite to model the intricacies of target interactions. Molecular dynamics simulations are typically employed to study protein dynamics at an atomic detail but are limited to time scales shorter than many biologically relevant conformational changes and by the size (number of atoms that can be simulated) of the protein of interest (Shaw et al. 2010). Therefore, it is computationally intractable to explore the extensive conformational fluctuations CaM undergoes to interact with target molecules by using all-atomistic molecular dynamics simulations. An alternative strategy is to employ a physics-based approach that utilizes low-resolution protein models to simulate the motion of CaM (and its targets). In this approach, each amino acid (except glycine) is represented by two beads: a α bead used to capture the trace of the protein backbone and a second bead that represents the size and chemical nature of the amino acid side chain (See Fig. 1). The van der Waals interaction between a pair of side-chain beads follows the Lennard-Jones potential, and their strength of interaction depends on the amino acid sequence (chemical environment). The interaction between α beads captures the hydrogen bonding between the two intervening backbones. The potential for the backbone retains partial information from the experimentally determined structures. The Brownian motion of individual atoms within the model is described by the Langevin equations of motion where the effect of solvent is implicitly represented through friction and agitation:

$$m \frac{d^2 X(t)}{dt^2} = -\nabla U(X) - \gamma \frac{dX(t)}{dt} + R(t).$$

In this formula, X is the position of the beads at time t , m denotes the mass of the bead, $U(X)$ is the potential of the system, γ is the friction coefficient, and $R(t)$ is the random force caused by the agitation of solvent at a certain temperature. The trajectories

can be computed by the integration of the equations of motion. This coarse-grained molecular simulation can be employed to efficiently explore a wide range of structures in solution while still preserving information of protein conformation pertinent to a global minimum on the folding energy landscape. This level of detail is indispensable to capture the conformational fluctuations employed by CaM as it searches for binding to individual targets.

The modeling strategy is further expanded with quantum chemistry calculations to capture the charge distribution of residues in the Ca^{2+} -bound state of CaM (holoCaM) (Wang et al. 2011). Additionally, computations can be made of the electrostatic interactions between charged residues modulated by the ionic strength in solution. The electrostatic interaction V_{ij} is represented by a Debye-Hückel (Debye and Hückel 1923) term in the potential of the system:

$$V_{ij} = \frac{z_i z_j}{4\pi r \epsilon_0 \epsilon_r} e^{-r} / \sqrt{\epsilon_r \epsilon_0 k_B T / 2eI}.$$

Z_i (Z_j) is the partial charge on each bead i (j), r is the separation between beads i and j , ϵ_0 is the permittivity of free space, ϵ_r is the relative dielectric constant, k_B is the Boltzmann constant, T is the temperature, e is the charge of an electron, and I is the ionic strength of the aqueous solution. In employing such simulations, it was shown that at higher ionic strength electrostatic repulsions are screened which results in stability increases and a more extended conformation of CaM. In this situation, CaM would more likely bind to target molecules that favor the extended conformation, a determinant in the process of ultimately dictating target selectivity.

Because of the computational efficiency of this strategy, it is also possible to address issues such as how the effect of excluded volume of surrounding macromolecules (Minton 1981) would impact the distribution of CaM conformations. As one example, incorporating Ficoll 70, an inert, nonpolar polymer, into the simulation environment can simulate macromolecular crowding. In this example, a simple hard-sphere model of Ficoll 70 (impenetrable hard spheres with a radius of 55 Å) is utilized to reduce the computational

demand while efficiently retaining its excluded volume effect. Coarse-grained molecular simulations showed that, at levels of crowding comparable to those predicted inside cells, apoCaM favors a more compact conformation and as a consequence would favor binding to targets where CaM must adopt a more compact form (Homouz et al. 2009).

Based on a combined approach of coarse-grained molecular simulations, energy landscape theory, and experiments, it will be possible to determine the number and probability distribution of unique conformations that will dictate how CaM chooses to distribute among the many possible intracellular targets. Ultimately, multi-scale computational models will be needed that can combine the oscillatory nature of the Ca^{2+} fluctuations and subsequent binding to CaM with the molecular level simulations of CaM and target protein structural fluctuations.

Definition

The membrane capacitance results from the fact that the plasma membrane acts as a capacitor: the

phospholipid bilayer is a thin insulator separating two electrolytic media, the extracellular space and the cytoplasm. The membrane capacitance is proportional to the cell surface area and, together with the membrane resistance, determines the membrane time constant which dictates how fast the cell membrane potential responds to the flow of ion channel currents.

Detailed Description

Membrane capacitance is the electrical capacitance associated with a biological membrane, expressed in units of Farads (F). The electrical capacitance of a biological membrane results from the membrane composition of a bilayer of mostly phospholipids that form an insulating matrix to which proteins are attached or embedded. The total membrane capacitance c_m of a cell is a quantity directly proportional to the membrane surface area and the dielectric properties of the membrane, provided that the thickness of the membrane is constant. Thus, the total membrane capacitance is $c_m = C_m A$, where C_m is the specific membrane capacitance (typically expressed in units of $\mu\text{F}/\text{cm}^2$) and A is the area.

Because of its linear relationship with cell surface area, capacitance is often measured experimentally as a way of determining cell area and thus cell size if the cell geometry is simple, for example, spherical or cylindrical (Streit and Lux 1987), or changes in membrane surface area (Neher and Marty 1982). These changes can be global or local, for example, when cells grow dendritic branches or add or remove membrane due to endocytosis or exocytosis at a synapse. Cell capacitance may also change due to local membrane thickness variations at lipid rafts, which are $\sim 10\%$ thicker than non-raft membranes (Alberts et al. 2008).

Because membrane capacitance determines the time constant of a neuron ($\tau_m = r_m c_m$), it plays an important role in the integration of the electrical inputs a neuron receives. It also determines the propagation velocity of action potentials which is inversely proportional to c_m (Matsumoto and Tasaki 1977). Finally, cell capacitance is a crucial parameter in detailed conductance-based

computational models, which are widely used to understand the activity and output of complex neuronal systems (Koch 1999).

To determine the exact surface area of a cell, a precise value of the specific membrane capacitance is required. A number of different methods can be used to determine the exact capacitance value, but in such calculations the fact that cell membrane surface – particularly in neurons – is rarely restricted to simple shapes should always be considered. In fact, the area of neurons is almost always distributed over surfaces that are intricate and complex, which affects the accuracy of capacitance measurements.

Measurement of Membrane Capacitance

A capacitor accumulates charge proportional to the voltage across it:

$$Q = c \cdot \Delta V \quad (1)$$

The rate of change of the capacitive charge is the capacitive current:

$$\left[I_c = \frac{dQ}{dt} = c \frac{dV}{dt} \right] \quad (2)$$

From this basic concept, several time-domain methods have been derived to measure the capacitance of a neuron, which essentially measure I_c under voltage clamp conditions.

1. Voltage ramp method. If a voltage ramp with slope dV/dt is applied to a capacitor in parallel with a resistor (an RC circuit), the current response generated includes a step whose amplitude is equal to the capacitive current I_c (Fig. 1a, red), followed by a ramp proportional to the conductance ($1/R$) of the circuit (Fig. 1a). From eq. 2, c can then be calculated.
2. Voltage step method. If a brief voltage step is applied, an initial current transient will be generated which is primarily the current that charges the capacitor (Fig. 1b). By integrating the area under the curve of this transient current ($\int I_c dt$, Fig. 1b, red), the charge Q can be measured and then used to determine c from Eq. 1.

Capacitance, Membrane, Fig. 1 *Capacitance measurement protocols. Top traces show stimulation waveform. (a–c), voltage clamp protocols. (d), current clamp protocol. Time scales for the different protocols differ, with (a) and*

(d) typically being slower (seconds) than (b) and (c) (tens to hundreds of milliseconds). Red indicates the response element relevant for the measurement of capacitance

3. Voltage sine wave method. If a sinusoidal voltage waveform is applied to an RC circuit, the current response will also be sinusoidal but shifted relative to the voltage input by a constant time (Δt , Fig. 1c, red). The resulting phase change is related to the capacitance of the circuit (Neef et al. 2007). Lock-in amplifiers in combination with voltage clamp devices generate outputs that are proportional to both impedance and phase, and thus capacitance can be determined (Neher and Marty 1982; Neef et al. 2007).

All voltage clamp methods give accurate measurements of capacitance in cells that are electrically compact (isopotential) and therefore can be described as single-compartment RC circuits. This is the case for many cell types, but is almost never true for neurons whose extensive processes (dendrites and axon) render them non-isopotential. For non-isopotential cells all these methods are inaccurate. Intuitively, the reason for this inaccuracy is that, at locations distal from the point of current injection (i.e., the site of electrode impalement), the membrane voltage decays along the processes relative to the

command voltage. The inability to maintain a constant voltage throughout the cell is referred to as the space clamp problem.

As an example, for a simple cell that can be represented by two compartments, one near and one far from the point of current injection, connected by a resistor, r_a , the total capacitance measured with voltage clamp methods can be approximated by

$$\left[c_m = c_n + c_f \frac{1}{(1 + r_a/r_f)^2} \right] \quad (3)$$

where c_n is the capacitance of the compartment near the point of current injection and c_f and r_f are the distal compartment capacitance and membrane resistance, respectively (Golowasch et al. 2009). Thus, the farther the distal compartment, and the lower its membrane resistance, the bigger the error in total capacitance. For cells with more complex morphological structure than two connected compartments, the measured capacitance deviates from the approximation given by Eq. 3. An estimate of the capacitance measured in voltage clamp in cells of more complex morphology is provided by Taylor (2012).

Current clamp method. A much more accurate method for measuring capacitance is current clamp pulses. It is appropriate even for cells that have their capacitance distributed over several distal compartments (Golowasch et al. 2009). The principle behind this method is that during a current pulse currents rapidly flow axially along the different cable-like structures of a cell and “equalize” the voltage. These currents generate voltage changes that can be described by multiple exponential terms with short time constants (Rall 1977; Holmes et al. 1992). Meanwhile, the membrane is slowly charged homogeneously over the entire surface of the cell, a process that can be characterized by an additional exponential change of the membrane potential, which has the slowest time constant of all the exponential terms. Thus, the membrane potential V_m can be described as a sum of exponential terms plus the resting potential V_{rest} :

$$V_m(t) = V_{rest} + \sum_{i=0}^{\infty} V_i \left(1 - e^{-t/\tau_i}\right) \quad (4)$$

By dividing Eq. 4 through by the external current I_{ext} , one obtains a series of resistive terms $R_i = V_i/I_{ext}$. The time constant of the slowest exponential term τ_0 is equal to the product $\tau_m = r_m c_m$, and r_m can be determined as the resistive component of the slowest exponential term (R_0), and $c_m = \tau_m/r_m$ (Golowasch et al. 2009).

All these methods rely on manipulating voltage in a range where only passive properties of the cell are involved. Any activation of voltage-gated currents will introduce significant errors in the capacitance estimate (Golowasch et al. 2009; White and Hooper 2013).

Specific Membrane Capacitance

The value most used is $1 \mu\text{F}/\text{cm}^2$, which most likely stems from the first measurements ever made in the famous series of experiments of Hodgkin, Huxley, and Katz published in 1952 (Hodgkin and Huxley 1952; Hodgkin et al. 1952). They in fact measured values over a range of 0.8 and $1.5 \mu\text{F}/\text{cm}^2$, with a mean of 0.9

$\mu\text{F}/\text{cm}^2$ (Hodgkin et al. 1952), but then used $1 \mu\text{F}/\text{cm}^2$ to simplify the complex calculation used for their final and seminal paper (Hodgkin and Huxley 1952). Later on it was shown that most cells do not have a smooth membrane whose area can be measured optically by making a simplifying geometric assumption (e.g., a perfect cylinder or a perfect sphere). Instead, most cell membranes have a certain degree of rugosity (lack of smoothness), which could lead to an overestimate of the specific membrane capacitance value. Using an inflation method in the whole-cell patch clamp configuration, Solsona and collaborators (Solsona et al. 1998) determined the specific membrane capacitance value to be closer to $0.5 \mu\text{F}/\text{cm}^2$. Furthermore, it has been established that cell capacitance does not significantly vary as a function of ion channel density (Gentet et al. 2000), and the value of $0.5 \mu\text{F}/\text{cm}^2$ obtained from inflated cells is close to that measured in artificial lipid bilayers although this value also depends on lipid composition (Niles et al. 1988).

Definition

The generation of the heartbeat is generated by cellular level electrical activity in the form of action potentials that arises as a result of timed opening

and closing of a variety of cardiac ion channels. When this tightly coupled interplay of ion channels is perturbed by any number of varied mechanisms including, but not limited to, genetic perturbations, altered Ca^{2+} signaling, deranged subcellular signaling, disruptions in cell ultrastructure or coupling, ionic dysregulation, or direct insult, an arrhythmogenic substrate can develop.

Detailed Description

Ionic Mechanisms of Cardiac Action Potential

Action potentials can be divided into non-contractile pacemaker cells and contractile cells that require an external stimulus, such as atrial and ventricular cells (Demir 2004). Numerous action potential morphologies exist and vary depending on the location in the myocardium. The action potential of contractile cells generally has 4 phases. Phase 0 is the rapid depolarizing phase resulting from fast Na^+ channel activation that causes rapid depolarization of the cell membrane potential. Phase 1 occurs when Na^+ channel inactivate, and K^+ ions pass outward through I_{to} (transient outward currents, which underly the notch found in some ventricular cell types). Phase 2 is marked by a phase of high resistance corresponding to the action potential plateau that is maintained by inward T-type and L-type Ca^{2+} currents and outward delayed rectifier K^+ currents. This critical phase permits the phenomenon of Ca^{2+} -induced Ca^{2+} release that couples electrical activity to cardiac contraction. Phase 3 is marked by inactivation of Ca^{2+} currents and larger K^+ currents that bring on the final repolarization phase of the action potential, allowing the cell to return to its resting potential in phase 4.

Perturbations in Ion Channels and Associated Processes Cause Disease

A wealth of basic scientific investigations have revealed that aberrant ion channel gating can result from naturally occurring mutations in the genes encoding cardiac ion channels leading to cardiac arrhythmias (Noble and Rudy 2001;

Priori et al. 1999a, b). Importantly, ion channels also interact with, and are regulated by, accessory proteins that dynamically influence the action potential. Many such examples of indirect perturbations underlying disease exist over the wide range of cardiac ion channels. Since they cannot all be covered in this brief overview, we will describe some perturbations affecting cardiac Na^+ current mutations as paradigms for the types of perturbations that have been linked to cardiac electrophysiologic pathology.

Since 1995 (Bennett et al. 1995), more than 200 mutations have been linked to SCN5A, the gene encoding the cardiac Na^+ channel α subunit on chromosome 3p21 (Wang et al. 1995). Initially segregated into distinct disease phenotypes such as long-QT3 syndrome (LQT3), Brugada syndrome (BrS), progressive cardiac conduction defect (PCCD), sick sinus syndrome (SSS), atrial fibrillation, and dilated cardiomyopathy (DCM), it is now known that multiple genetic defects can lead to overlapping syndromes with multiple clinical characteristics existing in one patient (Ruan et al. 2009).

LQT3 is a subset of the congenital long QT syndrome and is characterized by a delay in cardiac cellular repolarization, leading to cardiac arrhythmias and sudden death, often in young people. It has been proposed that delayed ventricular repolarization promotes a substrate for triggered activity via early afterdepolarizations (EADs), which result from reactivation of L-type Ca^{2+} channels (Thomas et al. 2007; Viswanathan and Rudy 1999; Lankipalli et al. 2005).

The first identified mutation in SCN5A, consequently shown to be a LQT3 variant, was ΔKPQ , a 3 amino acid deletion (lysine, proline, glutamine at positions 1505–1507) in the linker region between domains III and IV (Bennett et al. 1995). This motif is known to be critical for fast inactivation of the Na^+ channel, and this mutation results in persistent non-inactivating current (Bennett et al. 1995) (termed channel “bursting”) during normal cellular repolarization.

While the ΔKPQ mutation is one example of altered gating, evidence suggests that mutation-induced gain of function in cardiac I_{Na} can exist in at least three distinct forms. In addition to channel

bursting, a second abnormality in Na^+ channel gating that has been elucidated and linked to phenotype results from steady-state channel reopening called window current (Ruan et al. 2009; Wang et al. 1996). Window currents arise as a result of reopenings that occur over voltage ranges where steady-state inactivation and activation overlap. A third original mechanism was demonstrated in channels containing the I1768V mutation, which does not result in an obvious gain of channel function. However, experiments and mathematical simulations revealed that under nonequilibrium conditions during repolarization, channel reopening results from faster recovery from inactivation at membrane potentials that facilitate the activation transition (Clancy et al. 2003).

In each of these mechanisms, pathologic late Na^+ current due to channel reopening causes severe prolongation of the AP plateau (demonstrated on the body surface ECG as QT interval prolongation) and sets the stage for potentially deadly arrhythmic triggers (Clancy et al. 2003).

In contrast to LQTS-associated mutations that cause a gain of Na^+ channel function, mutations that have been identified in patients with congenital forms of Brugada syndrome (BrS) result in a loss of Na^+ channel function (Tateyama et al. 2004; Vecchietti et al. 2007; Liu et al. 2002). BrS is an arrhythmic syndrome characterized by right bundle branch block, ST-segment elevation on the ECG, and ventricular tachyarrhythmias that result in sudden death (Brugada et al. 1998). The reduction in I_{Na} has been shown to occur by several mechanisms in BrS, including reduced rates of recovery from inactivation, faster inactivation subsequent to channel opening, and protein trafficking defects (Clancy and Kass 2002; Grant et al. 2002; Tan et al. 2001; Bebarova et al. 2008).

BrS may result in heterogeneity of repolarization across the right ventricular myocardial wall. Repolarization in the epicardial cell layer is thought to be more sensitive to suppression of the peak Na^+ current due to a more prominent transient outward K^+ current (I_{to}) (Yan and Antzelevitch 1999). Mutations in SCN5A that reduce the peak I_{Na} could selectively hasten the repolarization in the epicardium, leading to a loss of the epicardial action potential plateau phase and an increased propensity

towards reentrant arrhythmias. This theory may explain the ST-segment elevation resulting from a dispersion of action potential plateau potentials observed in patients with BrS.

Another proposed mechanism underlying the Brugada syndrome phenotype is that loss of Na^+ current, observed as a depolarizing shift of the channel activation curve, may result in sufficiently slow conduction such that some areas of the myocardium are undergoing repolarization, while others are still depolarizing (Zhang et al. 2007). Indeed, a simulation-based investigation of this mechanism was investigated and shown to be plausible and account for the observed ST-segment elevation in these patients (Zhang et al. 2007; Petiprez et al. 2008; Miyoshi et al. 2005).

Heterogeneity of Ion Channel Expression in the Heart: Dispersion of Action Potential Morphology Leading to Arrhythmia

It has been shown experimentally that the myocardium displays distinct cell types that are heterogeneous in ion channel expression across the ventricular wall. This heterogeneity plays a key role in the normal sequence of ventricular excitation and in arrhythmogenesis (Noble and Rudy 2001; Antzelevitch et al. 1999). Potassium currents (I_{Kr} and I_{Ks}) in particular, which are essential in ventricular repolarization, show marked differences in expression between endocardial, mid-myocardial, and epicardial cells (Liu and Antzelevitch 1995). Midmyocardial cells, for example, have reduced I_{Ks} density and display longer APD than other cell types, and these differences in multicellular models can give rise to transmural heterogeneity which may contribute to the arrhythmogenic potential in long-QT syndrome (Viswanathan and Rudy 1999, 2000).

Mutations Can Result in Multiple Phenotypes

The relationship between genetic mutations and clinical syndromes is complex, as the revelation of

novel mutations suggests paradoxical phenotypic overlap or exclusivity. Multiple loci in the cardiac Na^+ channel have been identified where the same mutation can result in different disease phenotypes. An insertion of an aspartic acid residue (1795insD) in the carboxy terminus of $\text{Na}_v1.5$ can result in either BrS or LQTS (Bezzina et al. 1999). Additionally, mutation of the same residue to a histidine (Y1795H) or cysteine (Y1795C) results in BrS and LQTS, respectively, indicating the proximal region of the C-terminus as a potentially important structure in sodium channel function (Roden et al. 1996). Further review can be found in Moreno and Clancy (2009).

Calcium Dynamics and its Regulation of the Na^+ Channel

The changing dynamics of calcium during the cardiac action potential is a complex and highly coupled system that includes L- and T-type Ca^{2+} currents, ryanodine receptors, $\text{Na}^+/\text{Ca}^{2+}$ exchangers and SERCA pumps, Ca^{2+} -binding proteins and buffering with calmodulin and troponin, and multiple sarcoplasmic reticulum (SR) subspaces (Rice and Jafri 2001). Each of these processes has the potential to alter electrophysiological homeostasis and lead to arrhythmia.

Ca^{2+} modulation of the Na^+ channel has been demonstrated after direct binding sites for Ca^{2+} (Wingo et al. 2004), and the Ca^{2+} -binding protein calmodulin (CaM) (Mori et al. 2000) was found on the carboxy terminus of the Na^+ channel. These discoveries led to studies that revealed inactivation of I_{Na} can be modulated by Ca^{2+} , CaM, and/or the Ca^{2+} /CaM/CaM-kinase signaling cascade (Undrovinas and Maltsev 2008; Wagner et al. 2006; Maltsev et al. 2008).

In studies examining the interaction of the Na^+ channel and I_{NaL} with CaMKII, it was found that CaMKII coimmunoprecipitates and phosphorylates Na^+ channels (Wagner et al. 2006). Overexpression of CaMKII δ_C in rabbit myocytes (acute) and transgenic mice (chronic) led to (1) enhanced I_{NaL} , (2) slowed fast inactivation (but enhanced intermediate inactivation), (3) slowed recovery from inactivation, (4) shifted

steady-state availability in hyperpolarizing direction that was Ca^{2+} dependent, and (5) a rise in intracellular Na (Undrovinas and Maltsev 2008; Wagner et al. 2006); importantly, these results were reversible with CaMKII inhibition (acute only). Interestingly, Bers and Grandi (2009) note the striking similarity of these CaMKII-induced changes with the LQT3- and Brugada-linked mutant 1795insD (Bezzina et al. 1999). Maltsev and Undrovinas (Maltsev et al. 2008) found that in both normal and failing canine ventricular myocytes, the Ca^{2+} /CaM/CaMKII signaling cascade increased I_{NaL} and Na^+ influx by slowing inactivation kinetics, but conversely found a positive shift in the steady-state availability curve (Undrovinas and Maltsev 2008; Maltsev et al. 2008). Evidence of CaMKII upregulation has been confirmed in other studies examining the effects of CaMKII in the heart failure setting (Ai et al. 2005; Currie et al. 2004; Kirchhefer et al. 1999).

Conclusions

Understanding how perturbations to cardiac ion channels emerge as altered behavior in higher dimensions of cardiac tissue and lead to pathophysiology including cardiac arrhythmia and heart disease is a critical area of research. The ubiquity of ion channels throughout all excitable tissue and the myriad mutations that lead to disease that have thus far been discovered have provided a tremendous substrate for a fundamental understanding of ion channel biophysics. The challenge continues to be integration of fundamental mechanisms at the ion channel scale to the complex emergent phenomena of arrhythmia in higher dimensions.

Cardiac Excitable Tissue Pathology (Ischemia)

Byron N. Roberts and Colleen E. Clancy
Department of Pharmacology, University of
California, Davis, CA, USA

Definition

Ischemia is a condition that results when tissue is inadequately perfused with blood, leading to insufficient delivery of oxygen and necessary components, as well as impaired removal of metabolic waste products. In the context of cardiac tissue, ischemia can produce derangements of electrical activity, reduced mechanical pumping ability, myocardial infarction, and sudden cardiac death.

A wealth of experimental data has been generated describing the fundamental structural and functional changes that occur in cardiac tissue during ischemia. However, it is increasingly clear that the many complex changes that occur during the time course of ischemia and their resultant effects on emergent electrical and mechanical functioning in the heart cannot be fully observed or readily predicted via study of constituent elements alone. For this reason, a number of modeling and simulation studies have been undertaken to reveal fundamental biological principles and mechanisms of functional changes observed in cardiac ischemia and to predict how interactions between system components contribute to pathological electrical and mechanical changes in cardiac cells and tissue. Modeling and simulation have also been used to predict emergent disease processes and treatment effects in ischemia. At present, there is no alternative, efficient, and cost-effective experimental or clinical strategy that can achieve these goals. Enabling computationally based investigations are advances in numerical techniques and computing (Nivala et al. 2012; Abramson et al. 2010; Rocha et al. 2011; Neic et al. 2012), the implementation of customizable solvers such as Continuity (<http://www.continuity.ucsd.edu/Continuity>), modeling platforms like CHASTE and OpenCMISS

(Bernabeu et al. 2009; Bradley et al. 2011), and infrastructures aimed at facilitating standardization, interoperability, and dissemination of models (e.g., CellML and FieldML) (Bernabeu et al. 2009; Bradley et al. 2011; Christie et al. 2009; Quinn et al. 2011; Wimalaratne et al. 2009).

Detailed Description

Effects of Derangements to pH and Phosphometabolites

During ischemia, one of the initial changes in the cardiac cell is the acidification of both the intra- and extracellular compartments (Carmeliet 1999). This acidification is the result of increased proton production inside the cell as it undergoes a shift from mitochondrial to glycolytic ATP production, which is exacerbated as proton-absorbing phosphocreatine (PCr) is depleted. Some increased proton production is compensated for by the sodium-hydrogen exchanger (NHE), which moves sodium into the cell and exports protons, a process that promotes extracellular acidification. Shaw and Rudy initially developed mathematical models that incorporated electrophysiological intracellular pH modulation of membrane components to investigate pH effects on excitability of cardiac cells and tissues (Shaw and Rudy 1997a, b).

More recently, Crampin and Smith developed a computational model of cardiac acidosis that includes a dynamical model of pH regulation via inclusion of model representations of NHE as well as the sodium-bicarbonate symporter (NBC), anion exchanger (AE), and chloride-hydroxide exchanger (CHE) – all of which respond to changes in pH (Crampin and Smith 2006). The model simulations predicted effects of changes in pH on the time course of key ionic species during acidosis, including intracellular protons, sodium, and calcium. The Crampin and Smith model also incorporated dynamic models of direct and allosteric regulation of subcellular components by pH, including the sodium-calcium exchanger (NCX), sodium-potassium pump (NaK), SERCA pump, and ryanodine receptors (RyRs), which all exhibit decreased function at subnormal pH. In addition, the model integrated experimentally

observed pH-dependent changes in the conductance and/or gating kinetics of key cardiac ionic currents (e.g., I_{Na} , I_{Ca} , I_{to} , I_{Kr} , I_{Ks} , I_{K1}). This model was then used to make predictions about the effect of acidosis on electrophysiology and calcium cycling, the latter of which is a surrogate readout for excitation-contraction coupling (Crampin and Smith 2006; Crampin et al. 2006). Simulations suggested that critical to suppressed contractility are elevated sodium, inhibition of sodium-calcium exchange, and the direct interaction of protons with the contractile machinery.

A key calcium cycling component from the Crampin and Smith model, the cardiac sarcoplasmic/endoplasmic calcium (SERCA) pump, was subsequently modeled in more detail with particular inclusion of multiple phosphate species (MgATP, MgADP, and Pi) to allow detailed computational investigations on effects of altered metabolic function on the SERCA pump (Tran et al. 2009). Model predictions from this study showed that binding of MgATP had a large inhibitory effect on the maximal reverse rate of the SERCA pump. During ischemia, when ATP availability is low, reverse SERCA flux would be more prominent. This pathological effect is expected to contribute to calcium overload and resultant calcium-dependent arrhythmias observed in ischemia.

Another pH derangement in ischemic tissue is impaired proton removal that is exacerbated by the sustained presence of carbon dioxide in ischemic tissue (Carmeliet 1999). The recent modeling and simulation study by Roberts and Christini incorporated dynamic concentration changes for extracellular carbon dioxide and bicarbonate into the Crampin and Smith model (Crampin and Smith 2006) and then utilized the model to show how NHE inhibitors, which have been expected to reduce ischemia-reperfusion injury through normalization of Na homeostasis, made things worse by prolonging intracellular acidosis because of impaired proton removal. The resulting prolonged acidosis was predicted to inhibit multiple subcellular components, especially NaK (which is responsible for removing sodium), with the unintended and paradoxical consequence of perpetuating sodium overload (Roberts and Christini 2011).

Roberts and Christini also applied a comprehensive ischemia-reperfusion model that incorporates both pH- and phosphometabolite-dependent effects to dissect out specific roles for pH- or phosphometabolite-related processes in generating changes in excitability and action potential morphology that are associated with ischemia-linked development of cardiac arrhythmias (Roberts and Christini 2012). The model predictions suggested that phosphometabolites played a larger role than pH changes in persistent shortening of APD, reduction of action potential amplitude (APA), and depolarization of the resting membrane potential. Reduced phosphometabolite availability and pH recovery were predicted to affect multiple ion channels and exchangers. Some of these effects were the result of direct modulation by phosphometabolites and/or acidosis, while others resulted from elevated sodium and calcium loads during reperfusion. The results from Roberts and Christini suggested that therapies directed at increasing phosphometabolites availability during reperfusion may be more beneficial than aiding pH recovery with regard to mitigating action potential changes that increase the likelihood of reentrant arrhythmias.

Accumulation of Extracellular K

One of the hallmark indicators of ischemia in cardiac tissue is an increase in extracellular potassium that arises from impairments in cellular metabolism and predisposes the heart to lethal arrhythmias (Kleber 1983; Cascio et al. 1992). Hyperkalemia depolarizes the resting membrane potential, which reduces sodium channel availability and cell excitability. The consequent depression in upstroke velocity, coupled with decreased cellular coupling in response to low pH and ATP availability (Sugiura et al. 1990; Swietach et al. 2007), leads to a significant – and potentially proarrhythmic – reduction of tissue conduction velocity (Kagiyama et al. 1982; Carmeliet 1999).

Shaw and Rudy developed an ionic-based theoretical model of the cardiac ventricular cell to simulate conditions of acute ischemia including accumulation of extracellular potassium, acidosis,

and anoxia and to predict and examine their effects on ion concentrations, ionic currents, and the cardiac action potential (Shaw and Rudy 1997a). They used the model to predict the underlying ionic mechanisms responsible for reduced excitability and shortening of the action potential duration. Shaw and Rudy showed that extracellular potassium accumulation was the primary effector of cell excitability by depolarizing resting membrane potential and reducing sodium channel availability. Additional depression of excitability was induced by acidosis. Major changes in action potential duration were predicted by the model to be caused by anoxia-dependent opening of the ATP-sensitive potassium current ($I_{K(ATP)}$), consistent with predictions from an earlier simulation study by Ferrero Jr et al. (1996).

Potassium accumulation exhibits a multiphasic time course resulting from a presumed combination of three mechanisms that includes (1) increased K(+) efflux, (2) decreased K(+) influx, and (3) reduction in the volume of the extracellular space. Because the relative contributions of each of these mechanisms have been challenging to determine experimentally, modeling and simulation studies have been undertaken to predict how ionic mechanisms contribute to accumulation of extracellular potassium. Terkildsen et al. (2007) developed a model that was used to simulate changes in metabolite concentrations during acute global ischemia and investigate their effects in a dynamic model of cellular electrophysiology. The model incorporated a metabolically sensitive description of the Na(+)-K(+) pump and ATP-sensitive potassium current, in addition to cell volume regulation to allow a quantitative description of ischemic hyperkalemia. Simulations predicted that reduced NaK activity plays the largest role in extracellular potassium accumulation, followed by increased potassium efflux via $I_{K(ATP)}$ and a shrinking extracellular space due to cell swelling.

Reactive Oxygen Species

Reactive oxygen species (ROS) play a role in ischemic tissue pathology and result from increased production (e.g., increased free radical

generation) coupled with reduced availability of scavenging compounds (Murphy and Steenbergen 2008). ROS can damage the cell membrane via lipid peroxidation and increased leakiness and has been implicated in the collapse of mitochondrial function (Akar and O'Rourke 2011; Xie and Akar 2010; Akar et al. 2005; Aon et al. 2006, 2009). Modeling and simulation have been important tools to investigate how metabolic dysfunction that originates in the mitochondria can disrupt cardiac electrophysiology and lead to arrhythmias (Zhou and O'Rourke 2012). Zhou et al. formulated a model of the cardiac action potential in which a novel link between the membrane potential of the mitochondrial and the cellular membrane was established (Zhou et al. 2009). The model predictions suggested that effects of oxidative stress on mitochondrial membrane potential are a primary mechanism for shortening of the cellular action potential duration and suppression of cellular electrical excitability (Zhou et al. 2009).

Zhou et al. subsequently developed a reaction-diffusion mathematical model of ROS-induced ROS release in the mitochondrial network and demonstrated that such a model was sufficient to reproduce the experimentally observed emergent macroscopic properties of the mitochondrial network (Zhou et al. 2010). Model simulations were also used to confirm experimental observations that suggested depolarization waves of the mitochondrial membrane potential could arise (similar to cell membrane in cardiomyocytes) following stimulation with localized laser-flash or antioxidant depletion. Moreover, the model predicted similar sensitivity of the wave propagation rate to changes in quantities including superoxide, diffusion, production, and free radical scavenging to that observed experimentally. Finally, the model predicted novel mechanisms for synchronization of electrical activity, arising from clusters of oscillating mitochondria that entrain neighboring mitochondria.

Oxidative stress that occurs during ischemia can also result in modification of ionic components both directly and indirectly through activation of modulatory cell signaling pathways. Because these networks of interactions are

extraordinarily complicated and typically studied in isolation in experiment, computational modeling approaches have been used to predict effects of ischemia-linked oxidation on emergent properties of cardiac cells and tissues. Christensen and coauthors undertook a modeling and simulations studies that predicted effects of alterations in the cardiac Na current by oxidized calmodulin kinase II (CaMKII) (Christensen et al. 2009). The model predicted that phosphorylation of Na channels by oxidation-activated CaMKII causes a reduction in Na channel availability, a reduction in cellular excitability, and a slowing of conduction velocity of excitatory waves in tissue, increasing the likelihood of conduction block in the ischemic border zone.

Wagner et al. subsequently used a combined experimental and computational approach to probe the role for ROS-activated CaMKII effects on Na overload that is commonly observed in ischemia (Wagner et al. 2011). The model showed that although ROS-activated CaMKII effects on Na current may play a role in Na overload in the cells, the model suggested that this mechanism alone was not sufficient to account for the large increases in Na observed experimentally.

Disruption of Electrical Function and Arrhythmia Triggers

A number of modeling studies have been undertaken to better understand how single-cell electrical changes translate to tissue-level pathologies during ischemia (Shaw and Rudy 1997b; Romero et al. 2009; Rodriguez et al. 2004; Jie and Trayanova 2010). Shaw and Rudy carried out simulations in a multicellular one-dimensional ventricular fiber representation to determine mechanisms of slowed conduction and conduction failure during acute ischemia (Shaw and Rudy 1997b). They simulated conditions of elevated extracellular potassium, acidosis, and anoxia. The model predictions suggested that elevation in extracellular potassium was the major determinant of conduction, causing supernormal or depressed conduction, and was the only factor that could singularly cause conduction block when extracellular potassium varied within the

range reported for acute ischemia. This study demonstrated the potential for cardiac L-type Ca^{2+} current to support conduction of excitatory waves and defined a “safety factor” for conduction that accounts not only for various ionic currents but also the source-sink relationship in coupled tissue.

The source-sink relationship and its link to reentry vulnerability were explored in another modeling and simulation study by Romero et al. (2009). These simulations suggested that the source-sink relationship was the ultimate cause of the unidirectional conduction block that can lead to reentrant arrhythmias.

The most dangerous arrhythmias that arise during ischemia are ventricular tachycardia and fibrillation. These arrhythmias can be caused either by rapid repeated activation of an abnormal (ectopic) self-exciting region, or they can manifest as reentrant arrhythmias. During ischemia, afterdepolarizations can give rise to spontaneous excitatory waves if they excite a large enough region. Reentrant arrhythmias require such a trigger and are perpetuated by slowed conduction and unidirectional conduction block, mechanisms that have all been explored in quantitative detail using modeling and simulation approaches (Starmer 1997; Quan and Rudy 1990; Cherry et al. 2012; Jie and Trayanova 2010; Qu et al. 2006; Jie et al. 2008).

Mechanical Dysfunction

Ischemia produces profound effects on cardiac contractile function. Ischemia can produce an increase in diastolic pressure due to contracture, as well a reduction or absence of developed pressure (Allen and Orchard 1987). Mathematical models that contain explicit representations of cross-bridge formation and tension development have been used to better understand how ischemic metabolic pathology leads to impaired contractile force (Rice et al. 2008; Crampin and Smith 2006; Tran et al. 2010; Loiselle et al. 2008; Campbell et al. 2010; Ch'en et al. 1998).

Tran et al. developed a thermodynamically consistent and metabolite-sensitive model of cardiac cross-bridge cycling to explore the influence

of ischemic metabolites on force production under normal and ischemic conditions (Tran et al. 2010). The model recapitulated many of the experimentally observed effects of MgATP, MgADP, Pi, and H^+ on force development and retained the force/length/ Ca^{2+} properties of earlier models upon which the formulation is based (Rice et al. 2008; Crampin and Smith 2006; Loiselle et al. 2008; Ch'en et al. 1998). The model simulations suggested that the force-MgADP relationship (positive or negative) depends on the concentrations of the other metabolites and $[H^+]$.

During ischemia, afterdepolarizations can give rise to a spontaneous excitatory wave, and if the ectopic focus spreads to a large enough region, it can trigger a lethal arrhythmia. A three-dimensional tissue model incorporating mechanosensitive channels and regional ischemia has been used to study how mechanoelectrical feedback can trigger premature ventricular beats and have the potential to trigger reentry (Jie and Trayanova 2010; Jie et al. 2010).

Conclusions

Understanding how ischemia-induced alterations in multiple cardiac components emerge as altered behavior in higher dimensions of cardiac tissue and cause pathophysiology—including cardiac arrhythmia and mechanical dysfunction is a critical area of research. The ubiquity of pathological ischemia as a disease process affecting most excitable tissue and the myriad perturbations that occur simultaneously make this a disease that can benefit from modeling and simulations approaches to improve the fundamental understanding of the disease process and to reveal experimentally testable targets for therapy.

continuous range, the potential set of possible behavioral options is discrete. The neuroscientific study of decision-making draws heavily on the fields of psychology, economics, statistics, and ecology. Neuroscientific approaches to decision-making aim to reveal computational principles that can be mapped onto their neurobiological implementation.

There are two dominant traditions in neuroscience and psychology to study categorical decisions: perceptual and value-based decision-making. Perceptual decision-making focuses on how accurate decisions are reached by resolving perceptual uncertainty. In value-based decision-making, the stimuli themselves are not ambiguous, rather the value or utility of different options needs to be estimated based on prior experience. In both cases, the goal is to systematically manipulate different features of the environment in order to understand how they guide behavior.

Categorical Decisions

Paul Masset¹ and Adam Kepecs²

¹Watson School of Biological Sciences, Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, USA

Definition

Categorical decision-making is the process of committing to a particular option from a discrete set of alternatives.

Detailed Description

Introduction

Studies of categorical decision-making attempt to understand behavior by probing how different features of complex and changing environments guide the selection of choices. While the parameters underlying these features often span a

Behavioral Tasks for Studying Categorical Decisions

Both traditions of decision-making have extensively used two-alternative forced choice (2AFC) task designs. 2AFC is the simplest task in which the process of a decision between alternatives can be studied. In a 2AFC task, the subject is forced to make a choice between two alternatives based on the stimulus she has experienced.

An example of a widely used perceptual decision-making task is the visual random dot task (Newsome et al. 1989; Gold and Shadlen 2007). In this task an ambiguous perceptual stimulus is instantiated by a cloud of moving dots. Subjects are asked to report whether the apparent motion is to a given direction or its opposite. A random process controls the moment-to-moment movement of individual dots. The strength of apparent motion and hence stimulus discriminability are controlled by the fraction of coherently moving dots. To perform correctly on the task, subjects need to view the stimulus over some period of time to extract the direction of coherent motion.

Categorical Decisions, Fig. 1 (a) Schematic of the random dot task. Foreperiod: a fixation point appears at the center of the screen. Delay: once the subject fixates the point, the two saccade targets appear on either side of the fixation point. The trial is ready to start. Motion: the cloud of randomly moving dots appears. A subset of these dots moves coherently in the direction of one of the saccade

targets. Choice: the subject makes a saccade to one of the two targets. In this paradigm, the integration of evidence occurs during the stimulus presentation. (b) Schematic of matching task. Foreperiod and delay: same as in (a). Choice: the subject makes a saccade to one of the two targets. In this paradigm, the integration of evidence occurs by integration over the previous outcome history

An example of a value-based decision-making task is the matching paradigm in which subjects have to choose between two options that differ in the probability and size of rewards (Platt and Glimcher 1999; Sugrue et al. 2004). Both reward probability and size are set by the experimenter and change across trial blocks. Here a subject has to integrate across trials (and not across time within a trial) to infer the value of the stimuli and make the correct choice (Fig. 1).

Models of Decision-Making

Computational studies of decision-making in neuroscience often focus on algorithmic descriptions of the decision process and attempt to describe both behavior and its neural correlates.

Models of perceptual decision-making describe how ambiguous perceptual information is processed and leads to the selection of a choice. At every instant, a subject extracts some features from the stimulus that will form the evidence that guides the decision-making process. One popular class of models that have been proposed to describe how the evidence is used is based on sequential sampling

(Bogacz et al. 2006). They have been chiefly motivated by sequential probability ratio test, in which the ratio of the probability of possible alternatives is computed as evidence is accumulated. These models can be solved as a first passage time problem; a commitment to a decision occurs once the probability ratio reaches a set value. As shown in Eq. 1, the decision variable $V(t)$ is updated by integrating the momentary evidence $e(t)$. Once the decision variable reaches a set bound B , the corresponding alternative is chosen and the response is initiated (Eq. 2). More complex models have been developed taking into account physiological characteristics such as adaptation and the role of time in the decision process (Drugowitsch et al. 2012; Brunton et al. 2013).

Accumulation:

$$\frac{dV}{dt} = e(t) + \text{noise} \quad (1)$$

Decision rule:

$$V(t) \geq B \quad (2)$$

These models have been popular, as they can account for the dependence on the stimulus of

both the choice and the reaction time (t_{choice} where $V(t_{\text{choice}}) = B$). They also explain the widely observed trade-off between the speed and accuracy of decisions. A lower threshold B implies that less accumulation of evidence is necessary to commit to a decision, which leads to faster reaction times at the expense of reduced accuracy. Neural recordings have revealed evidence for the existence of such accumulators in neural circuits implicated in perceptual decision-making (Gold and Shadlen 2007).

In value-based decision-making, models have used ideas from *reinforcement learning*. In a matching task, even if a full model of the task structure is not available to the subject, a reinforcement-learning algorithm can estimate the values of the stimulus features. The value of a stimulus is the subjective utility of its outcome, which needs to be estimated based on experience. There is a large class of reinforcement-learning model, but the simplest and most often used one is *temporal difference learning* (TDRL). As shown in Eq. 3, the update rule for the value $V(T)$ of each alternative after trial T has two terms. The first is an update term that depends only on the previous outcome history. It is a *temporal discount*, proportional (with a constant γ) to the value of the previous trial $V(T - 1)$. The second term is the *prediction error* δ , which is proportional (with a constant α) to the difference between the outcome $r(T)$ and the expected outcome computed from the outcome history $V(T - 1)$. Once the value of each option is computed, the choice is made using a decision rule that optimizes the behavior according to the task contingencies. The decision rule often represents a trade-off between exploiting the currently available evidence that leads to larger reward (e.g., selecting the option with the highest value, $\text{choice} = \text{argmax}(V_i)$) and balancing exploitation with exploration using a probabilistic decision rule (e.g., selecting an option with a probability given by a softmax rule where $P_{\text{Choose } R} = e^{V_R/\beta} / (e^{V_R/\beta} + e^{V_L/\beta})$, and β controls the trade-off between exploration and exploitation, or by a relative value rule where $P_{\text{choice} = R} = (V_R / (V_R + V_L))$ (Lee et al. 2012).

TD learning:

$$V(T) = \gamma V(T - 1) + \alpha \delta(T) \quad (3)$$

$$\delta(T) = r(T) - V(T - 1) \quad (4)$$

Decision rule:

$$P_{\text{Choice} = R} = \max(V_R, V_L) \text{ or } \frac{e^{V_R/\beta}}{e^{V_R/\beta} + e^{V_L/\beta}} \text{ or } \frac{V_R}{V_R + V_L}$$

Despite its simplicity, this model is able to predict trial-to-trial variation in behavior in value-based decision-making tasks. For instance, an implementation of TDRL with the relative value decision rule ($P_{\text{Choose } R} = (V_R / (V_R + V_L))$) can account for the observation that the ratio of responses matches the ratio of inferred stimulus values (Sugrue et al. 2004). Importantly, fitting these models to behavior has enabled researchers to extract decision variables that can be mapped onto neural activity (Lee et al. 2012). For example, activity in the dopaminergic system correlates with the prediction error signal (Schultz et al. 1997), and activity in the lateral intraparietal cortex correlates with stimulus value in a matching task (Platt and Glimcher 1999; Sugrue et al. 2004).

These models describe the computations performed during the decision-making process but not their implementation at the neuronal level. Attractor networks, neural networks composed of spiking neurons connected through synapses, have been proposed as a biologically plausible implementation of these computations (Wang 2012). These neural networks implement dynamical systems on which sensory stimuli act as perturbations. Depending on their strength, these perturbations can push the network toward different attractor states leading to a categorical decision (Fig. 2).

Open Questions and Future Directions

Decisions are, given the available evidence, not always perfect. Understanding the sources of error, the sources of noise, and uncertainty in the behavior will be essential to understanding how

Categorical Decisions, Fig. 2 (a) Stimulus: the stimulus is being sampled. Evidence: the relevant parameters from the stimulus are extracted to obtain the momentary evidence at a given time. Integration: the evidence is integrated over time to obtain the decision variable. Race to bound: once the decision variable reaches a predetermined bound the corresponding action is selected. (b) Outcome

history: the subject has an internal representation of the outcome history. Integration: the outcome history is integrated over past trials to obtain a decision variable. Value computation: the value of each alternative is computed using the integrated outcome history. Decision rule: the probability of making a given choice is a function of the computed values that depends on the decision rule used

decisions are computed in the brain. In the two frameworks presented above, noise has distinct origins. In perceptual decision-making, the sensory perception itself can be noisy. In value-based decision-making, the external world environment can be stochastic, or the internal model of the task contingencies may be incorrect (Beck et al. 2012), leading to suboptimal behavior. Stochastic behavior, however, can also be advantageous in competitive environments so that competitors are not able to predict choice behavior. Understanding the contribution of different sources of noise to decisions is an exciting direction in the field.

Although reaction time is often used as a critical constraint for models of decision-making, there are multiple processes contributing to it, including non-decision time, such as the time required for movement planning. Clever behavioral manipulations can be used to separate different components of reaction time and reveal that simple discriminations can unfold in as little as 30 ms (Stanford et al. 2010).

The goal of models is to provide trial-by-trial accounts for behavioral outputs rather than just fitting averages and observed distributions of decision variables. Models, however, may be underconstrained when only using categorical choices as behavioral readouts of graded decision

variables. Additional variables, such as reaction time (Gold and Shadlen 2007), confidence report (Kepecs and Mainen 2012), or changes of mind (Resulaj et al. 2009), can be used to further constrain models. Using these variables can improve trial-by-trial fits, identify different sources of noise, and help us understand the computational processes supporting decision-making.

CCDB

Definition

The Cell Centered Database (CCDB; <http://ccdb.ucsd.edu>) project was launched in 2002 to provide online repository of high-resolution 3D light and electron microscopic reconstructions of cells and subcellular structures (Martone et al. 2002, 2003, 2008). The CCDB was designed to complement the structural databases of gene, protein, and tissue structure by hosting data in the dimensional range known as the “mesoscale,” roughly encompassing the structures that sit between gross morphology and molecular structure, e.g., cellular networks, cellular and subcellular microdomains along with their macromolecular constituents. The study of mesoscale structures continues to present a challenge to experimentalists, because to build a comprehensive understanding of complex tissues in this dimensional range requires the ability to aggregate data obtained by multiple researchers across techniques and spatial scales.

Detailed Description

The types of imaging data stored in the CCDB are quite heterogeneous, ranging from large-scale maps of protein distributions taken by confocal

(Orloff et al. 2013) microscopy to 3D reconstruction of individual cells, subcellular structures, and organelles reconstructed using electron tomography, time series of subcellular dynamics, and a growing collection of serial block face electron microscopic datasets (e.g., <http://ccdb.ucsd.edu/sand/main?mpid=8244&event=displaySum>). While many of the datasets in the current CCDB derive from the nervous system, reflecting our own area of expertise, the schema of the CCDB is essentially agnostic with regard to cell type.

From its inception, the CCDB envisioned that it would be part of a series of distributed databases that could be cross-queried and navigated and has worked actively to integrate with other relevant resources. In 2012, the CCDB joined with the Cell

Image Library (CIL: <http://cellimagelibrary.org>), developed by the American Society of Cell Biology. All public CCDB data is now available directly through the CIL and through CIL's cell-centered interface (Fig. 1), which additionally hosts over 10,000 additional images of cells and tissues. The CIL provides an easy to use graphical interface, where users can browse contents by clicking on various organelle systems in a graphic of a eukaryotic and prokaryotic cell. Datasets in the CIL are annotated with terms from 14 different ontologies in 16 different fields as well as a basic description and technical details. CCDB is also registered with the Neuroscience Information Framework (<http://neuinfo.org>) as part of its extensive data federation. Currently, the CCDB

Cell Centered Database, Fig. 1 The CCDB may be accessed through its home page (upper left), via the Cell Image Library interface (middle panel) or via the

Neuroscience Information Framework (bottom). Through CIL and NIF, CCDB data is linked to other relevant data at different scales and systems

and CIL are maintained as separate resources, but we are working to merge the front and back ends to provide a unified resource for cellular imaging data.

In addition to the public CCDB, the CCDB also maintains a private space available via the CCDB portal (<http://ccdb-portal.crbs.ucsd.edu/>). Private space is used for the data management pipeline for the National Center for Microscopy and Imaging Research (<http://ncmir.ucsd.edu>). Private space is also used for registration of datasets prior to publication. Once data are approved, they are released to the public site.

Although the predominant data type housed within the CCDB is imaging data, the CCDB

was not designed to be a simple image repository, that is, the data model is not designed for the storage of individual images. Rather, it is designed around the process of 2D, 3D, and 4D reconstruction from light or electron micrographs, capturing key steps in the process from experiment to analysis. At the center of the CCDB data model is the “microscopy product” table. The microscopy product refers to a set of related 2D images taken by light (epifluorescence, transmitted light, confocal, or multiphoton) or electron microscopy (conventional or high-voltage transmission electron microscopy). For each type, the images comprising a single microscopy product are systematically related to each other along a single

Cell Centered Database, Fig. 2 Organization of search results through the CCDB interface. Users are shown thumbnails for the types of data available for each

microscopy product. In this case, the 2D dataset, 3D reconstruction, and segmentation are all available

dimension. For example, a tilt series contains images that are related to each other through a tilt angle; a mosaic contains images that are related through X, Y coordinates, and optical section, through focus and serial section series contain images that are related through Z depth. A given set of data may be more than one product, for example, it is possible for a set of images to be both a mosaic and a tilt series.

Linked to each microscopy product are any reconstructions and analysis products, e.g., segmentations and models, created from either the raw data or the reconstruction. The CCDB makes the 2D image datasets, reconstructions, and segmentations available for viewing and download (Fig. 2). Because each project may have different aims, the CCDB does not require that all types of products be available for each dataset. The microscopy product identifier serves as the accession number for the CCDB. This value was chosen because a given dataset may only be taken once, and therefore, each microscopy product represents a unique dataset. In contrast, multiple reconstructions may be derived from a single microscopy product, and multiple segmentations may be derived from a single reconstruction.

The CCDB was designed with an eye towards encouraging reanalysis and reuse of mesoscale data and for mining the content of these datasets. Towards this end, the CCDB provided not only the final data product, usually a 3D reconstruction, but the raw data, specimen preparation details, the imaging parameters, and any derived data products created as a result of analysis of the reconstruction. Thus, the schema of the CCDB ensures that researchers can trace the provenance of a piece of data and understand the specimen preparation and imaging conditions that led to it while making raw and derived data available for reanalysis.

Data from the CCDB/CIL is available free of charge for browsing online and for download and reuse through a CC-BY license. Users should cite the CCDB accession number and acknowledge both the CCDB and the data contributor in any subsequent use. CCDB/CIL encourages submissions from the biological imaging community and accepts high-quality imaging data regardless of

whether they are part of a published study. Submitted data are curated and annotated by staff prior to release. If data are part of a published study, the CCDB/CIL can provide an accession number and private review space for use during the review process. Data will be released to the public upon publication.

CellML

Randall D. Britten

Auckland Bioengineering Institute, University of Auckland, Auckland, New Zealand

Definition

CellML is a format for specifying mathematical models, focusing on the needs of systems biology, but applicable to a broader range of fields that use mathematical modeling. It focuses on models that are formulated as ordinary differential equation (ODE) systems and differential algebraic equation (DAE) systems. Please see Miller et al. [2013](#) for more details. (Note that the article mentions some of the tools that were available for working with

CellML at the time it was written. Specifically, it mentions OpenCell and COR. Since then, these two projects have been merged into a single project called OpenCOR.)

Definition

Center-surround processing (CSP) describes the integration of localized “center” with contextual (“surround”) information into a more global representation. It has been studied mostly as a sensory computation, in particular in the early visual system (Carandini et al. 2005). Although center and surround are often defined in space, CSP is a more general processing in the sense that it is also

performed in other physical dimensions such as in the auditory domain or in time (Schwartz et al. 2007). In neuroscientific contexts, CSP is defined rather mechanistically as the difference between the processing of localized and extended stimuli. Signatures for CSP are found in many different brain areas, where the responses of neurons to a localized stimulus are strongly and often nonlinearly influenced by its context. Computationally, these processes are thought to be essential for constructing complex, global representations in higher brain areas (i.e., the perception of “objects”) from simple, local features forming the sensory input.

Detailed Description

CSP can be introduced and studied from two different perspectives:

- From neurophysiological and psychophysical evidence: Experiments reveal a rich repertoire of cases where the surround of a stimulus influences the brain’s processing of the center of a stimulus. Important examples are antagonistic (► [Retinal Neurophysiology](#)) receptive fields (► [Spectrotemporal Receptive Fields](#) ► [Receptive Field Modeling](#)) of retinal ganglion cells (► [Retinal Neurophysiology](#)) which have different polarities in center and surround (e.g., Geffen et al. 2007), non-classical receptive fields in the visual cortex (► [Hierarchical Models of the Visual System](#)) revealing strong nonlinearities in the integration of center and surround (e.g., Freeman et al. 2001), and enhanced or reduced visibilities of target stimuli induced by the presence of flanking elements in psychophysical studies (e.g., Polat et al. 1998).
- From theory and first principles: Information integration becomes necessary if “global” information is distributed over many “local” channels such that the knowledge of information in one local channel is not sufficient to recover the “global” information in an unambiguous way. CSP is a special form of information integration, with the additional

requirements that there must be some form of topology (in order to define center and surround) and that there is a limited range over which information can be integrated. This perspective on CSP is explored in normative approaches (► [Bayesian Approaches in Computational Neuroscience: Overview](#); ► [Cortical Function, Normative Models of](#); ► [Visual Illusions, Models of](#)), e.g., probabilistic modeling, with strong conceptual cross-links to Gestalt psychology (► [Visual Illusions, Models of](#)).

The definition of center and surround strongly varies among studies – it can be defined in terms of the stimulus components used in an experiment, in terms of the synaptic input fields of a neuron (or population), in terms of a cell's response properties or receptive field organization, or in terms of the modulation of the neuronal response by stimuli presented outside the receptive field (the “nonclassical receptive field”). CSP is not restricted to concentric arrangements, even if the name suggests this specific form for center-surround (CS) interactions.

The following paragraphs will explain various aspects of CSP within different concepts and theoretical approaches, in an attempt to structure research on CSP. Note that these aspects are not isolated from each other but have mutual cross-links.

From Image Processing to Object Recognition

In (applied and neural) image processing, CSP plays a fundamental role in both preprocessing and in higher-order computations performed on a visual scene. The simplest CS computations can be expressed as linear spatial filters applied to an input. For example, a Mexican hat (► [Center-Surround Processing, Network Models of](#); ► [Flicker-Induced Phosphenes](#)) filter, which can be realized as a Difference-of-Gaussians (DOG) (► [Center-Surround Processing, Network Models of](#); ► [Flicker-Induced Phosphenes](#)) M (Fig. 1a) defined as

$$M(x) = A_+ \exp\left(-\frac{|x|_2}{2\sigma_+^2}\right) - A_- \exp\left(-\frac{|x|_2}{2\sigma_-^2}\right)$$

can be used for edge enhancement, data compression, decorrelation (► [Sensory Coding, Efficiency](#)), and whitening (► [Independent Component Analysis of Images](#)):

- Edge enhancement: Mexican hat with zero integral, applied to images, completely suppress regions with homogeneous content, as, e.g., uniformly painted walls or open sky. Edges or any other discontinuities, however, are enhanced by this filter (Fig. 1c). In discrete representation, the Mexican hat acts like a Laplacian operator which computes the second spatial derivative (curvature) of a two-dimensional function.
- Data compression (e.g., Zhaoping 2006): If an image is composed of many regions with homogeneous content (see paragraph above), as is typical for natural scenes, the output of a DOG filter will yield few values which are substantially different from zero, namely, at locations with discontinuities. The image representation will thus become compressed or sparsified (► [Independent Component Analysis of Images](#)) (Olshausen and Field 1996). The term sparse denotes a representation in which only few units (or neurons) are active, while all other units are (almost) silent (e.g., Rozell et al. 2008).
- Decorrelation (spatial and temporal): In most natural image ensembles the light intensities of neighboring locations are highly correlated, even over long distances. DOG filters reduce these spatial correlations as well as temporal variations in light intensities which are shared by a region of pixels in an image.
- Whitening (e.g., Graham et al. 2006): Natural images typically have power spectra exhibiting power law characteristics. DOG filters with increasing amplitudes for higher spatial frequencies can be used to decompose the image into spatial frequencies and then to selectively enhance higher-frequency image content to achieve a flat power spectrum whitening (► [Independent Component Analysis of Images](#)), Fig. 1c).

**Center-Surround Processing,
Computational Role of,**

Fig. 1 From image processing to object recognition. **(a)** Mexican hat function (difference of Gaussians) which is positive in the center (*red*) and negative in the surround (*blue*). **(b)** ON- and OFF-center receptive fields of retinal ganglion cells. Stimulating with a bright spot in the RF's center leads to an increased firing rate for the ON center and to a decreased firing rate in the OFF-center cell. Conversely, stimulating with a bright spot in the surround leads to a decreased firing rate in the ON center and to an increased firing rate in the OFF-center cell (Kretzberg and Ernst 2013) (Textbook Neurosciences, Springer 2013, Box 18.2a). **(c)** Comparison between a whitened image (*right*) to the original image (*left*). The whitened image contains far less pixel values that are different from the background level than the original image (Olshausen and Field 1996) (<http://redwood.berkeley.edu/bruno/sparsenet/>). **(d)** Example for image spots selected by the SIFT algorithm as suitable, characteristic descriptors for a visual scene (Wikipedia, accessed 6 Oct 2013, http://en.wikipedia.org/wiki/Scale-invariant_feature_transform. The image was published under the Creative Commons License)

More complex operations are achieved by non-linear CSP. Robust image processing often requires computations to be invariant against changes in illumination, spatial scale, contrast, or other properties of a scene which are unimportant for a certain (recognition) task. One example is divisive normalization (► [Color](#)

[Vision, Computational Methods for](#); ► [Computation with Population Codes](#)) or inhibition where the output of a unit processing the “center” is divided by the summed output of units processing the surround. Divisive normalization plays an important role for achieving contrast-invariance of a preceding filter operation, which is, e.g.,

Center-Surround Processing, Computational Role of, Fig. 2 Feature integration and Gestalt psychology. (a) Dot pattern visualizing the Gestalt law of proximity. In the left pattern, the horizontal spacing of the dot grid is smaller than the vertical spacing. In consequence, the dots are perceived as being grouped in horizontal lines. The effect reverses in the right pattern, where spacing in the vertical dimension is smaller. (b) Stimulus used to study contour integration (Emst et al. 2012): in a background of randomly oriented edge elements (*Gabor patches*), a horizontal contour of colinearly and cocircularly aligned edges has been embedded. Superimposed is an association field, which visualizes the typical interactions needed to integrate the local edge elements into the global percept of a contour. (c) Association field computed from natural image statistics. This association field was derived from the pairwise edge statistics of contours labeled by human observers as belonging to the same object. The color denotes the likelihood ratio of having an edge with the corresponding orientation and distance to a horizontal edge in the center of the association field which belongs to the same contour, versus the same configuration

realized in neural responses to visual input patterns.

Most applied image-processing algorithms make heavy use of CSP in a hierarchical manner. Algorithms inspired by properties of the visual system include HMAX (Riesenhuber and Poggio 1999), SIFT, and HOG (Dalal and Triggs 2005). As an example, the Scale Invariant Feature Transform (SIFT) (► [Color Vision, Computational Methods for](#)) algorithm (Fig. 1d) builds on a sequence, or chain, of center-surround operations (Lowe 2004; Lindeberg 2012). Parts of this procedure are (a) DOG filtering on different spatial scales to find the so-called keypoint candidates (i.e., characteristic points of interest in a scene), then (b) detection of corners by inspection of the keypoint candidates' surrounding regions, and finally (c) the generation of “descriptors” by computing the differences between the local orientation of the image patch at a keypoint and the orientations of the surrounding patches. These CS operations realize the computational principles of (a) scale-invariance, (b) selection of salient features, and (c) orientation-/rotation-invariance, respectively.

Feature Integration and Gestalt Psychology

In the 1920s, a group of psychologists around Max Wertheimer (*1880, +1943) expressed a set of principles (Todorovic 2007) according to which basic image features (e.g., dots, edges, lines) are grouped by our visual system to facilitate higher-order cognitive functions such as figure-ground segregation or object recognition. For example, if dots are arranged on a regular grid, and if the horizontal (vertical) distance between these dots is slightly larger than the vertical (horizontal) distance, the dots are perceived as arranged in columns (rows). This phenomenon refers to the Gestalt law of “proximity” (Fig. 2a). Gestalt laws are linked to CSP by the fact that the surround of a feature (in the

← **Center-Surround Processing, Computational Role of, Fig. 2** (continued) occurring in the plain edge statistics (Geisler et al. 2006) (Geisler, Super, Perry and Gallogly, Vision Research 41 (2001), pp 711, Figure 3f)

above example, the proximity of neighboring elements) determines how the central part of a stimulus is perceived. Also in Gestalt psychology, surround refers not only to the dimension space but also to other dimensions such as time: Elements having the same motion vector (i.e., a “common fate”) are also likely to be grouped together. In the literature, such grouping processes often run under the terms feature integration or binding (see also Herzog 2009).

While Gestalt psychologists defined criteria of feature integration mostly in an empirical way, more recent work strives to ground Gestalt principles in natural scene statistics which then implies specific forms of CSP (Geisler et al. 2001; Sigman et al. 2001; Simoncelli and Olshausen 2001). Central idea is that the laws according to which the surround of a local image patch influences its processing shall be determined by the statistical properties of objects in natural scenes (if object recognition is the ultimate goal of visual processing). A good example for the close match between Gestalt processing and natural image statistics is contour integration ► “Somatosensory Cortex: Neural Coding of Shape”. Contour integration refers to the (cognitive) process which links oriented line segments that are aligned in colinear and cocircular way (thus obeying the Gestalt law of “good continuation”) (Fig. 2b). Computationally, contour integration can be performed using an association field that quantifies which particular configurations of two oriented edges are to be linked together (Field et al. 1993). Association fields extracted from psychophysical experiments closely match the pairwise edge statistics computed from human-labeled natural scenes (Fig. 2c) (Geisler et al. 2001).

Models emerging from the feature integration perspective on CSP are predominantly “bottom-up,” seeking to implement empirically observed principles of CSP in suitable neural architectures (Li 1998), but see also Ernst et al. (2012) for a normative approach.

Normative and Probabilistic Approaches

A different perspective on CSP emerges from normative frameworks for understanding brain

function. They predict properties of CSP from general principles for neural computation and cognition. A prominent example for a normative framework is the hypothesis that the brain holds an internal model of the outside world (von Helmholtz 1856) which is constantly matched to the signals received by our sensory system. Such an internal model could consist of the statistical properties of objects and their composition in natural scenes which are used to infer the presence (or absence) of these objects in a stream of action potentials (► Hodgkin-Huxley Model; ► Excitability: Types I, II, and III) from the retina.

In the framework of ► Bayesian Inference with Spiking Neurons, CSP emerges as a competition between neurons with input fields that overlap in their surrounds (Fig. 3a): Both neurons would respond equally when only the optimally matching center stimuli were presented alone, giving the same evidence for two potential explanations (Fig. 3a, left). The additional appearance of a surrounding stimulus would disambiguate the situation by giving more evidence for the first of the two explanations (Fig. 3a, right). In consequence, the responses will become modulated accordingly – the second explanation is made less probable and thus “explained away,” and the first explanation becomes more likely. This effect can account for a range of experimentally observed CS modulations.

While the objective of Bayesian frameworks is to perform statistical inference as best as possible, other objectives as, e.g., the goal to obtain a “sparse” representation also imply specific forms of CSP. In neurophysiological contexts, a sparse representation is beneficial to reduce the number of action potentials transmitted and thus energy consumption. On a conceptual level, sparsity is a suitable constraint for situations in which a scene that is represented by a flood of signals on the sensory levels can be equally well described by the presence of typically only a small number of objects efficient coding (► Efficient Population Coding) (Fig. 3b). Interestingly, requiring a sparse representation and performing optimal inference lead to similar dynamics in CSP (Lochmann et al. 2012; Zhu and Rozell 2013).

Center-Surround Processing, Computational Role of, Fig. 3 Normative and probabilistic approaches. (a) Contextual information integration and “explaining away.” In this simplified scheme, a generative model is shown with two possible causes (explanations) for a stimulus (observation): the presence of the words “tag” and “gut,” each having three letters. Given the clear evidence of only one letter “g,” these two explanations are equally likely (*left*). The additional, contextual evidence of the letter “a,” however, disambiguates the situation and increases the likelihood for the presence of “tag.” At the same time, this increased likelihood for “tag” explains away the presence of the letter “g” as evidence for “gut,” thus decreasing

its likelihood. **(b)** While neurons fire with high rates and more regular when stimulated locally within their classical receptive field (*top, left and right*), their activity becomes more sparse and more irregular for a (natural) stimulation which extends beyond their cRF (*bottom, left and right*), thus resembling more the typical activation patterns observed *in vivo* in a natural environment. This experimental observation (*left*, Vinje and Gallant 2000) (Vinje and Gallant, Science 18 (2000), 1273ff, Figure 1b/c) has recently been explained by “explaining away” in a normative model for contextual processing (*right*, Lochmann et al. 2012) (Lochmann, Ernst and Deneve, J. Neurosci 32 (2012), Figure 4d)

Taken together, one of the major factors shaping CSP in normative approaches is competition. Competition is realized by different mechanisms as, e.g., divisive and subtractive inhibition and unspecific and input-targeted inhibition (e.g., Carandini and Heeger 1994), and leads not only to suppression but also to enhancement of neural

responses. Together with the statistical properties of the elementary building blocks of natural scenes, normative frameworks currently provide a comprehensive account for CSP as performed in the early stages of the visual system (Srinivasan 1982; Rao and Ballard 1999; Spratling 2010; Lochmann et al. 2012; Zhu and Rozell 2013).

Center-Surround Processing, Computational Role of,
Fig. 4 Neurophysiological and psychophysical evidence for CSP. (a) Response of a V1 cell to circular gratings of increasing diameter, for low stimulus contrasts (blue) and high contrasts (red). Surround suppression thus depends on contrast, with the preferred stimulus size being larger for low contrasts (Shushruth et al. 2009) (Textbook Neurosciences, Springer 2013, Box 18.7c). (b) Typical,

idealized response pattern for an orientation-contrast sensitive cell as in Sillito et al. 1995, with the orientation of the center on the horizontal axis, and the orientation of the surround annulus on the vertical axis. Highest firing rates are observed if center and surround are orthogonal (red lines), lowest firing rates if center and surround have same orientations (blue line). (c) Contextual influences from the surround are seldom homogeneous, but can be divided into

Neurophysiological and Psychophysical Evidence for CSP

(a) Physiological Correlates

The response characteristics of neurons are often described in terms of their receptive fields (RFs) (► [Spectrotemporal Receptive Fields](#); ► [Receptive Field Modeling](#)). One distinguishes between the “classical” and “extra-classical” (or “nonclassical”) part of a RF (cRF and ncRF). Heuristically, the cRF describes the neuron’s response to localized and simple stimuli, while the ncRF characterizes the response characteristics for extended and complex stimuli. Technically, the cRF is obtained by using stimulation with sparse or dense noise stimuli and applying reverse correlation (► [Spike Triggered Average](#)) methods to compute the RF of a cell under a linearity assumption (i.e., that the response to arbitrary combinations of localized stimuli is the sum of responses to these stimuli presented in isolation). In essence, ncRFs are response properties which are not explained by this simple model – in particular, modulations of the neural response to stimulus components inside the cRF by stimulus components outside the cRF, which would give no response when presented alone (e.g., Sillito et al. 1995; Levitt and Lund 1997; Cavanaugh et al. 2002; Freeman et al. 2001; Series et al. 2003).

cRFs of neurons often reveal a concentric organization of their spatial receptive fields, in

particular neurons of the early visual system. A prominent example is retinal ganglion cells or neurons from the lateral geniculate nucleus (Fig. 1b). They are organized either in an ON-OFF or in an OFF-ON (antagonistic) layout, meaning that these cells respond preferentially to a bright spot on a dark background or to a dark spot on a bright background, respectively. Mathematically, such cRFs can be described with Mexican hat functions (see above). Antagonistic cRFs are not limited to vision, e.g., also neurons in the auditory system possess RFs in frequency space which resemble a one-dimensional cross section of a Mexican hat (Machens et al. 2004; Theunissen et al. 2000).

ncRFs come in many different varieties, and although they have extensively been studied in the visual system, there is yet no coherent empirical classification scheme. The following examples illustrate some prominent effects that were confirmed by different experimental studies, and for which normative (see above) or bottom-up modeling can provide a unifying account:

- Surround suppression (Fig. 4a): If a stimulus localized in feature space is made larger, the neural response initially grows, but then becomes more and more suppressed (e.g., Shushruth et al. 2009; Solomon et al. 2006). Typically, suppression is most pronounced when the stimulus extends beyond the cRF borders. If the stimulus consists of oriented features (i.e., gratings, bars), surround

Center-Surround Processing, Computational Role of, Fig. 4 (continued) “near surround” and “far surround.” On the left, model scheme for explaining the origin of differences between near- and far-surround interactions. On the right, responses of a V1 cell to a stimulus composed of a center grating and an annulus of same (preferred) orientation with decreasing inner radius, eliciting far-surround facilitation from about 8-deg. annulus width (Ichida, Schwabe, Bressloff, Angelucci, J. Neurophysiol 98, 2168ff(2007), Figures 1b and 2a right). (d) Orientation preference map and layout of horizontal connections of a layer II pyramidal cell in cat A17. Preferred stimulus orientation is coded according to the color palette in the lower right corner; the black bar corresponds to 500 μ m in

the cortex. The dendrites of the cell are shown in black, and its axon in white (This figure is courtesy of Dr. Zóltan Kisvarday and Ms. Kitti Csorba) (Textbook Neurosciences, Springer 2013, Box 18.8). (e) Example for crowding: the letters “H” have the same size and visual eccentricity from the red fixation spot. However, the right “H” is more difficult to perceive because of the presence of contextual information, i.e., the other letters. (f) Famous visual illusion, demonstrating the contextual influence of the lines in the background, suggesting depth in space, on size perception of the figures – although being of the same physical size, the right figure is perceived as being bigger than the left one

suppression is the strongest if these features are similar and the weakest or even opposite if these features are different. This effect might also depend on stimulus strength (or contrast). Changing the contrast can reverse the polarity of the modulation.

- Contrast enhancement (Fig. 4b): If the stimulus consists of components that are different (or orthogonal) in the surround, neural responses often become enhanced or disinhibited (e.g., Sillito et al. 1995). Computationally, contrast enhancement is similar to edge enhancement by DOG filtering, but extends to more complex feature combinations such as oriented gratings (corner detection).
- Sparsity of neural representation for natural scenes (Fig. 3c): Signatures of CSP are also revealed when stimulating visual cortical neurons with natural scenes. Responses are strong and sustained when neurons are stimulated with natural scenes seen through a circular aperture with a diameter matching their cRF. However, when the aperture is widened, the responses become weaker, more transient, and sparse, thus better matching the neural dynamics observed *in vivo* (Vinje and Gallant 2000).
- Near and far surround (Fig. 4c): In the visual cortex, the surround is further subdivided into a “near surround” and a “far surround.” These can have differential influence on firing rates, e.g., the far surround exerts an enhancement of neural activity, while the near surround suppresses neural responses (e.g., Schwabe et al. 2006; Ichida et al. 2007).

Note that this list is not complete and that there typically is a large amount of variability in ncRF properties even for neurons of one type in one particular brain area.

(b) Anatomical Correlates

CSP is at least partly mediated by the topology of anatomical connections between neurons within and between cortical areas. Typically, axons or dendrites extend radially from neural

populations and have different ranges for excitatory and inhibitory connections. This property naturally causes antagonistic response profiles in the afferent cells. Furthermore, connections were shown to be response specific: For example, excitatory long-ranging horizontal axons in the primary visual cortex preferentially connect neurons with similar cRFs (“neurons that fire together, wire together”) (Fig. 4d). Depending on the effective sign of these interactions, they might mediate surround suppression (see above), but also enhancement of colinear stimulus configurations as would be necessary for integrating contours.

(c) Psychophysical Evidence

Signatures of CSP are extensively studied with psychophysical methods (see paragraph above: Feature Integration and Gestalt Psychology). In the corresponding literature, these effects figure under various terms such as masking (the perception/visibility of localized stimuli depends on their spatial and temporal context), crowding (detection and identification of localized stimuli depends on the nature and density of flanking elements) (Fig. 4e), popout (a much higher saliency of certain feature combinations which are embedded in surrounding elements), fill-in (complementing missing sensory information by the brain), and others. Many visual illusions yield good examples for CSP (Bach 2013). At a first glance, they might be regarded as glitches of the visual system, but indeed are signatures that the brain does “its best” to make sense of artificially composed stimulus arrangements with a content that does not match normal experience or natural image statistics (Fig. 4f).

Definition

Surround modulations of neuronal responses by stimuli outside the receptive field are omnipresent

in sensory systems, and network models seek to explain them as an emergent network phenomenon. They are particularly useful because recurrent networks often behave counterintuitive, i.e., different from the neural dynamics assumed by phenomenological models.

Detailed Description

Lateral inhibition is an example of center-surround (CS) processing. As a perceptual phenomenon, it was already known to Ernst Mach in the mid-nineteenth century (Yantis 2014). The so-called Mach bands are a visual illusion, where the border between adjacent luminance-defined areas appears to have higher contrast than it actually has. Phenomenological models of this perceptual effect share the common idea of spatial filtering the input image (the visual sensory signal) with a symmetric center-surround kernel (Pessoa 1996). Such a filter-based description is agnostic regarding the actual neural mechanism, but network models with short-range excitation and long-range inhibition are plausible candidates for implementing them. End-stopped neurons in primary visual cortex (V1), first described by Hubel and Wiesel in 1965 (Hubel and Wiesel 1965), are another example, where the spatial surround of the receptive field modulates the strength and selectivity of orientation-tuned responses. Recent modeling studies emphasize the role of strong local and balanced intracortical feedback in surround modulation (e.g., Ozeki et al. 2009) and how it may interact with interareal feedback connections (Shushruth et al. 2012) in CS processing. Strongly recurrent neural networks can exhibit counterintuitive emergent properties that are not anticipated by the often implicitly assumed circuitry underlying, e.g., filter-based or other computational approaches to CS. The role of CS processing in perception could be the amplification of relevant stimulus features in noisy and cluttered environments such as figure-ground segmentation in vision. Hence, the explicit integration of different pathways in network modeling CS processing is a promising approach to understand how sensory systems

extract relevant information from noisy and cluttered environments.

Models of Center-Surround Processing in Early Vision

The signaling cascades in the retina triggered by photons impinging on photoreceptors are well characterized. For example, light falling onto cones leads to their hyperpolarization and a decrease in glutamate release onto bipolar cells. In response to this decrease, on-center bipolar cells depolarize, which leads to an increase of the glutamate they release onto retinal ganglion cells (RGCs). As a consequence, these RGCs are on-center cells that increase their spike discharge. Horizontal cells, contacted by the photoreceptors, inhibit neighboring photoreceptors. This explains

why a full illumination (causing lateral inhibition) leads to less RGC spikes than a spatially restricted illumination (with less or no lateral inhibition). Figure 1a illustrates the increase in RGC spike discharges in response to a visual stimulus and shows how cone photoreceptors, C, are connected to horizontal cells, H, and bipolar cells, B. This basic motif, namely, realizing suppression of responses to a large stimulus via inhibition of neighboring cells, has been very influential and was thus employed to explain surround suppression in the cortex as well.

Figure 1b (top) shows two image patches of different size. Within these patches the texture is dominated by an oblique orientation, a stimulus feature that triggers responses of orientation-selective neurons in primary visual cortex (V1). Interestingly, however, is the observation that orientation-selective V1 neurons with their

Center-Surround Processing, Network Models of,

Fig. 1 Illustration of three center-surround effects, each with a possible underlying network model. (a) The frequency of spike discharges of retinal ganglion cells (RGCs) increases when the center of the RGC's receptive field (RF) is illuminated (white dot) and returns to the pre-stimulus baseline when the illumination is turned off. When the center and the surround of the RF are illuminated, then the spike discharge does not increase (not shown). A retinal circuit model explains this selectivity via lateral inhibition: Light falls onto the cones, C, which triggers lateral inhibition of neighboring cones with horizontal cells, H. The on-center bipolar cells forward this signal to RGCs. (b) Responses of orientation-selective

neurons with RF center at location 2 (in the visual field) in primary visual cortex (V1) are suppressed when the size of the oriented texture is increased. The retinal circuit for lateral inhibition, Fig. 1a, is not directly applicable, because the horizontal connections in V1 are made only by excitatory cells. Those need to contact local inhibitory neurons to implement a "sign switch" that realizes the lateral inhibition. (c) Interconnected lateral inhibition circuits across different visual areas. The feedback connections from areas downstream to V1 are known to be spatially more extensive than the horizontal connections within V1 (Fig. 1b). Via such pathways the lateral inhibition can affect neurons with very distant RF centers

receptive field (RF) center at location 2 (Fig. 1b) *decrease* their spike discharges when the texture is increased in size. Hubel and Wiesel first described such a phenomenon in V1 of cats in 1965 (Hubel and Wiesel 1965). Qualitatively, this is the same phenomenon as the selectivity to illumination in the RF center of on-center RGCs: When the stimulated area in the visual field is increased, the response decreases. Experimental studies even support another analogy to the retinal circuit, namely, that the observed surround suppression in V1 may be inherited partly by surround suppression in the LGN (Webb et al. 2005) (as the suppression of RGCs is inherited from the lateral inhibition acting between their presynaptic cells).

Network models of surround suppression in V1 make use of the idea of lateral inhibition. In V1, however, the lateral connections to neighboring neurons (in terms of distinct neighboring RF centers) are made only by excitatory cells. One proposal has been that these lateral connections target local inhibitory neurons (Somers et al. 1998), which then perform a “sign switch” of this excitatory and horizontally propagating signal (Fig. 1b). The detailed layout of the topographic map in V1 determines how long such horizontal connections need to be in order to link neurons with different RF centers. Intracortical long-range connections (up to 2–3 mm in macaque V1) are widely believed to carry this horizontal signal, but much shorter connections (up to 0.25 mm) have been proposed as a potential substrate as well (Wieland and Sajda 2006). These shorter connections may account for some forms of surround suppression, but they fail to account for physiologically observed response suppression for large stimuli in which the surround is way beyond the reach of these short-range connections.

The role of short-range connections received renewed interest after a modeling study (Ozeki et al. 2009) that emphasized an apparently counterintuitive property of strongly recurrent networks of excitatory and inhibitory neurons (see the local coupling between E and I neurons in Fig. 1b). It was shown that an increased excitation of inhibitory neurons from outside the local recurrent circuitry, such as via the long-range horizontal connections, ultimately leads to a decrease of

both the excitatory *and* inhibitory responses, which can easily be understood using phase-plane analysis (Ozeki et al. 2009). While this study is still compatible with horizontal connections as the substrate of surround suppression in V1, it shows that network models need to be set up explicitly and analyzed rigorously to overcome the potentially too simplistic intuition that worked for simple circuits (e.g., Fig. 1a) but fails for strongly recurrent systems. Recently, this model has been used to investigate the orientation tuning of surround suppression (Shushruth et al. 2012).

Models of Center-Surround Processing Across Multiple Cortical Areas

For some forms of surround suppression observed in V1, the long-range horizontal connections may even be too short. Feedback connections from downstream cortical areas into V1 have been proposed as the substrate of lateral inhibition in cases when the stimulus in the surround is beyond the reach of the V1 horizontal connections (Schwabe et al. 2006), because this feedback is spatially even more extensive. Moreover, it may play a crucial role in center-surround processing in other conditions as well, in particular during natural vision. Figure 1c shows an image of a tiger almost hidden behind grass and the spatial extent of a RF in a visual area downstream to V1 (large red circle). The larger RF encloses a smaller RF in V1, which is located at the barely visible neck of the tiger. Surround suppression is known to enhance the responses to borders such as inside the RF of the V1 neuron. Due to the barely visible border, a global-to-local integration of spatially adjacent cues will be beneficial to enhance responses to elongated borders (the tiger’s neck) in cluttered scenes.

Modeling Techniques

For most of the effects described here, mean-field models that describe the dynamics of the average neural activity in a population of neurons are often sufficient. Some studies employ large-scale

simulations of networks of spiking model neurons. They are often biologically more appropriate as they can account for aspects that are hard to integrate into mean-field models such as heterogeneity of parameters.

Discussion and Future Directions

Given that strongly recurrent networks can have counterintuitive properties (Ozeki et al. 2009; Shushruth et al. 2012), it may be important to employ them as building blocks for larger models, including the neural mass models used in brain imaging. In particular, studying how adaptation at various time scales and via multiple mechanisms affects the effective network connectivity and hence the resulting center-surround computations is an important task for future studies. Finally, we need to understand how interconnected cortical areas collaborate in center-surround computations at each stage.

Central Vestibular Signal Processing

Rebecca Lim, Thomas P. Wellings and Alan M. Brichta
School of Biomedical Sciences and Pharmacy,
Hunter Medical Research Institute, The
University of Newcastle, Callaghan, NSW,
Australia

Definition

The *vestibular nuclear complex* (VNC) is a major site of central vestibular processing and traditionally consists of four major neuroanatomical regions: *medial*, *lateral*, *superior*, and *descending* (*spinal*) vestibular nuclei. However, recent cellular and molecular studies indicate that further subdivisions, based on more detailed analyses, better describe *functional groups* within these nuclei. The distribution of *calcium-binding proteins* and *marker genes* is redefining the VNC into specific regions with identifiable functional implications.

Detailed Description

The mammalian vestibular system is responsible for our sense of balance and can be divided into *peripheral* and *central* components (Goldberg et al. 2012). The *peripheral vestibular system* is located in the inner ear and composed of five sense organs (three semicircular canals and two otolith organs) that collectively generate signals in

response to rotational and translational head movements. These “balance” signals are then transmitted, via the eighth cranial nerve, to various targets in the central nervous system (CNS). Collectively, these CNS targets comprise the *central vestibular system* and are responsible not only for creating our perception of balance but also for contributing to the remarkably precise stabilization of gaze and posture, as well as general motor control (Cullen 2012; Goldberg et al. 2012).

Subdividing the Vestibular Nuclear Complex

Precisely how these complex and demanding functions are accomplished, particularly by the central vestibular system, is not understood. This is due in large part to our rudimentary understanding of the functional neuronal groups that constitute the central vestibular system. This lack of knowledge is best illustrated by the vestibular nuclear complex (VNC), a critically important brainstem region that distributes incoming peripheral vestibular signals to other parts of the brainstem, cortex, cerebellum, and spinal cord. Despite it being a major site for multisensory processing, we know very little about this region beyond the classical neuroanatomical studies that first described four major divisions or *vestibular nuclei* (Brodal and Pompeiano 1957). This lack of detailed knowledge is because it has been difficult to identify, classify, and manipulate functionally distinct cell types that are often spatially intermingled within the VNC (Kodama et al. 2012). In the last decade, however, immunohistochemical and molecular studies, together with electrophysiological analyses, have begun to identify discrete subdivisions within these individual vestibular nuclei and support the notion of a vastly more complex functional organization that has been long suspected (Scudder and Fuchs 1992; Bagnall et al. 2007).

Analysis of the Medial Vestibular Nucleus

Revealing the complexity of both functional organization and connectivity within the VNC

provides a much-needed cellular basis for understanding this pivotal central vestibular region. For example, one division of the VNC, the *medial vestibular nucleus* (MVN), can itself be further subdivided simply based on the individual neuron’s projection target. These targets include ocular motor neurons, cerebellar neurons, and local neurons within the ipsi- and contralateral VNCs (Highstein and Holstein 2006). Further subdivisions have also been described based on specific differences in intrinsic excitability across MVN neurons with different axonal projections and neurotransmitter (Takazawa et al. 2004; Sekirnjak and du Lac 2006; Bagnall et al. 2007; Kolkman et al. 2011a, b; Shin et al. 2011). Still other subdivisions have been demarcated by immunoreactivity (ir) to functionally important calcium-binding proteins (CBPs) such as *calbindin* (CB) and *calretinin* (CR). Subdivisions based on these CBPs have proved consistent across a number of species including rodents, cat, monkeys, and human (Resibois and Rogers 1992; Rogers and Resibois 1992; Kevetter 1996; Baizer and Baker 2005, 2006; Baizer and Broussard 2010) strongly suggesting a conserved purpose. While the function of these distinct CBP regions has yet to be determined, it has been suggested that regions with dense CB-ir represent a zone of dense cerebellar input (Baizer et al. 2013) and thus may play a role in adaptive modifications of reflexive eye movements (Rambold et al. 2002). While the CR-ir region is likely to receive direct peripheral vestibular input and project to other parts of the VNC and suggests a coordinating rather than command role in eye movement generation.

Functional Organization of the MVN Revealed by Combined Studies

Molecular studies are beginning to uncover further complexities in the internal organization of the VNC. In addition to classifying neurons into distinct subdivisions, molecular studies have the added advantage of ascribing these subdivisions particular functions. In a recent study by Kodama et al. (2012), using single-cell expression profiling

of genes related to neurotransmitters and ion channels, they were able to demonstrate candidate molecular markers that subdivided MVN into six distinct types. By combining this approach with anterograde and retrograde labeling techniques, they were able to determine the functional role of four out of the six molecularly defined classes of MVN neurons. The six types were identified as three classes of excitatory neurons (E1, E2, E3) and three classes of inhibitory neurons (I1, I2, I3), each associated with a specific set of marker genes. For example, E1 were large glutamatergic MVN neurons that uniquely expressed gene markers *Spp1* (*secreted phosphoprotein 1*) and *Slc17a6* (*vesicular glutamate transporter 2*) and projected to oculomotor or abducens motor nucleus, while glutamatergic E2 neurons expressed *Crh* (*corticotropin-releasing hormone*) and *Slc17a7* (*vesicular glutamate transporter 1*) and projected to the cerebellar flocculus.

Future Studies of the Central Vestibular System

As proposed by Kodama et al. (2012), this strategy of classifying neurons into functionally distinct groups could also be applied to any heterogeneous neuronal population, including those regions associated with central vestibular system. For example, quantitative single-cell transcript analyses, in situ hybridization, immunohistochemistry, and electrophysiological studies could be used to identify functional organization of neurons in the cerebellar and ocular motor nuclei, as well as higher cortical centers processing vestibular information. With the expanded knowledge promised by these combined studies, the chances of understanding how the central vestibular system unobtrusively achieves the extraordinary feat of creating our sense of balance and its attendant actions are becoming a realistic possibility.

Cercal System

Hiroto Ogawa¹ and John P. Miller²

¹Faculty of Science, Department of Biological Science, Hokkaido University, Sapporo, Japan

²Department of Cell Biology and Neuroscience, Montana State University, Bozeman, MT, USA

Definition

The cercal system is a mechanosensory system in orthopteran insects, which mediates the detection, localization, and identification of air currents surrounding the animals. The receptor organ for this modality is a pair of antenna-like appendages called *cerci* at the rear of the abdomen, covered with mechanosensory hairs like the bristles on a bottlebrush (Fig. 1). Air currents in the animal's immediate environment move these hairs and, thereby, activate the receptor neurons at the base of the hairs. The cercal system is implemented around an internal representation of stimulus direction and dynamics that demonstrates the essential features of neural maps found in more complex systems, including mammalian visual and auditory systems. Over the last several decades, this system of the cricket has been used as a simple “model system” for investigations of development, mechanoreceptor biomechanics, neural maps, and neural coding (Jacobs et al. 2008).

Detailed Description

Overview

The cercal system was shown in early studies to be of critical importance for the oriented escape response to air puffs (Hoyle 1958; Camhi 1980; Boyan et al. 1986). However, it is a considerable oversimplification to class this system as an “escape system.” Rather, the cercal system should be thought of as functioning as a low-frequency, near-field extension of the animal's auditory system. Air particle displacement directed at the cerci can elicit at least 14 distinct responses, including evasion, flight, offensive reactions, scanning, freezing, and various reactions during male stridulation, and response can depend on the behavioral state of the animal as well as the context of the environment (Baba and Shimozawa 1997; Casas and Dangles 2010). In addition to the filiform receptors sensitive to air particle displacement, bristle hairs, clavate hairs, and campaniform sensilla are distributed on the cercus. The cercal system is, therefore, also responsible for mediating behavior related to orientation relative to gravity as well as a variety of touch and chemotactic sensations via other types of sensors on the cerci (Murphey 1985; Sakaguchi and Murphey 1983; Heusslein and Gnatzy 1987). The detailed description of this topic will be limited to the sensory-processing system on direction and dynamics of airflow mediated by filiform receptors.

Functional Organization of the Mechanosensory Hair Array

In *A. domesticus*, the species used for most of the studies in the past, each cercus is approximately 1 cm long in a normal adult cricket and is covered with 500–750 filiform mechanosensory hairs (Palka et al. 1977; Miller et al. 2011). These hairs range in length from 50 μ m to 1.5 mm. Each hair is supported at its base by a viscoelastic socket that enables the hair to pivot within its socket, rather than bending along its shaft (Keil and Steinbrecht 1984). Each hair's directional movement axis is determined by the orientation of a hinge-like structure in the socket. The 750 hairs on each cercus are arrayed with their movement axes in diverse orientations within the

Cercal System, Fig. 1 The cricket cercal system. (a) *Gryllus bimaculatus* (female). The cerci are the two antenna-like structures, covered with fine hairs, extending from the rear of the abdomen. (b) Computer reconstruction of the outline (blue) of a terminal abdominal ganglion (TAG) with several reconstructed nerve cells.

A reconstruction of a single identified giant interneuron (GI right 10–3) is shown in blue, and several filiform sensory afferent arbors are shown in other colors. (c) Micrograph of the GI left 10–2 and a filiform afferent stained with fluorescent dye

horizontal plane. On a global scale, the directionality of hairs is organized in bands along the long axis of the cerci. There is a systematic rotation in the movement directions of the hairs around the circumference of each cercus, and there is a non-uniform distribution of hair densities along the length of the cercus, with greater density nearer the base than near the tip (Palka et al. 1977; Miller et al. 2011). This global organization of the array insures that air currents of sufficient velocity will deflect *all* of the filiform hairs to some extent: each hair will be deflected from its rest position by an amount that is proportional to the cosine of the angle between the air current direction and the hair's movement axis.

Each mechanosensory hair is innervated by a single spike-generating mechanosensory receptor

neuron. These receptors display directional and dynamical sensitivities that appear to be derived largely from the mechanical properties of the hairs themselves (Shimozawa and Kanou 1984). The amplitude of the response of each sensory receptor cell to any air current stimulus depends upon the velocity and direction of that stimulus, and the directional tuning curves of the receptor afferents are well-described by cosine functions (Landolf and Jacobs 1995; Landolf and Miller 1995).

Representation of Stimulus Direction

The sensory afferents of filiform sensilla project in an orderly array into the terminal abdominal ganglion to form a continuous representation of the direction of air currents in the horizontal plane (Bacon and Murphey 1984; Jacobs and

Cercal System, Fig. 2 Anatomical prediction of synaptic connectivity between filiform sensory afferents and interneurons. **(a)** A reconstruction of GI right 10–2 shown in yellow and afferent arborizations from 12 different filiform hair receptors shown in different colors. The color of each

afferent corresponds to its direction of peak activation. **(b)** A reconstructed dendrites of GI right 10–2 within the afferent neural map of direction. The neural map is predicted by the “statistical cloud” corresponding to the density of synaptic terminals for that stimulus direction

Theunissen 1996, 2000; Paydar et al. 1999). The synaptic terminals from afferents having similar peak directional sensitivities arborize in adjacent areas, and the spatial segregation between afferent arbors increases as the difference in their directional tuning increases. A representation of the stimulus direction in a three-dimensional neural map of the entire filiform afferents has been developed, based on anatomical and physiological measurements taken from a large sample of individual afferents (Fig. 2; Troyer et al. 1994; Jacobs and Theunissen 1996; Paydar et al. 1999). By combining the predicted responses of each class of afferents with this information about the spatial location of their terminal arborizations within the neural map, predictions have been made of the spatial patterns of synaptic activation that would result from sustained, unidirectional air currents (Jacobs and Theunissen 2000; Paydar et al. 1999; Troyer et al. 1994). The predictions were consistent with spatial patterns of ensemble activity of filiform afferents visualized by calcium imaging experiments (Ogawa et al. 2006).

Dendritic Integration in the Giant Interneurons (GIs)

The 1500 sensory afferents synapse with a group of approximately 30 local interneurons, and

approximately ten pairs of identified ascending interneurons project their axons to motor centers in the thorax and integrative centers in the brain. These ascending interneurons have been called “giant interneurons” due to their large-diameter axons which enable very rapid conduction of action potentials to the higher ganglia. Like the afferents, these interneurons are also sensitive to the direction and dynamics of air current stimuli (Jacobs et al. 1986; Miller et al. 1991; Ogawa et al. 2004; Theunissen and Miller 1991; Theunissen et al. 1996). The directional sensitivity of the ascending interneurons is primarily based on the relative positions of their dendrites within the afferent map of the mechanosensory afferents (Fig. 2; Jacobs and Theunissen 2000). However, the overall directional tuning and dynamical sensitivity of each individual interneuron also depends on the spatial distribution of synapses onto the complex geometry of the dendritic arbors (Fig. 3; Ogawa et al. 2008). The frequency sensitivity of each interneuron depends on two independent factors: (a) its inherent frequency-filtering properties that are a function of intrinsic membrane properties and synaptic transmission characteristics and (b) the position of its dendrites within the afferent map.

Cercal System, Fig. 3 Relationship between electrotonic geometry of the dendritic arbor and directional tuning of dendritic Ca^{2+} responses in GI 10–3. **(a)**, images showing the compartment models of GI 10–3 with the spike-initiation zone (SIZ) indicated. **(b)**, plots of inward electrotonic distance (ED) versus path distance relative to the SIZ in the model of GI 10–3. The X axis is the path distance from the soma to the compartment along each process. **(c)**, polar plots indicate the mean number of spikes

(black line), and the mean amplitude of Ca^{2+} increases at three different dendrites X, Y, and Z (red, green, and blue lines, respectively). Each value of the Ca^{2+} - and action-potential responses was scaled to the maximal responses of each measurement. The curve shown by the orange line was predicted by calculating the weighted sum of the tuning curves of the individual dendritic responses based on electrotonic distances

Dendritic Ca^{2+} Elevation and Ca^{2+} -Mediated Adaptation

The excitation of GIs causes cytosolic Ca^{2+} elevation in their dendrites (Ogawa et al. 2000). Similar to the firing responses, dendritic calcium responses to the airflow stimuli also show direction sensitivity, which varies in their selectivity and preference direction depending on the dendritic location (Ogawa et al. 1999, 2004, 2008; Ogawa and Oka 2015). This detectable calcium elevation is mainly due to the influx of Ca^{2+} through voltage-gated Ca^{2+} channels activated by action potentials back-propagating into the dendritic arbor (Ogawa et al. 2000). Therefore,

the spatial heterogeneity of direction sensitivity in dendritic Ca^{2+} response is considered to be due to changes in the location of the spike-initiation site and/or the intra-dendritic spike-propagation dynamics depending on the airflow direction (Ogawa et al. 2002a, 2002b; Ogawa and Mitani 2015). Heterogeneous Ca^{2+} dynamics induces local Ca^{2+} accumulation during repetitive stimulation, which causes direction-specific attenuation of the GI's response via transient synaptic depression (Ogawa et al. 2001; Ogawa and Oka 2015). This mechanism provides a neural basis for direction-specific adaptation of the escape behavior to repetitive airflow stimulation.

Neural Encoding and Transmission

Some or perhaps all of the 20 projecting sensory interneurons in this system represent the general parameters of air currents via an ensemble coarse-coding scheme. For example, four GIs in a well-studied group (the left and right GIs 10–2 and 10–3) have been shown to be tuned broadly to the direction and velocity of bulk airflow movements and project a coarse-coded image of these parameters to higher centers that is accurate to approximately 8 degrees (Theunissen and Miller 1991; Theunissen et al. 1996). More recent research has demonstrated that these same four GIs (and perhaps all of the other projecting GIs) also respond with high sensitivity to complex dynamic multidirectional features of air currents on a smaller spatial scale than the physical dimensions of the cerci (Mulder-Rosi et al. 2010), using a coding scheme that is more complex than simple linear encoding (Aldworth et al. 2011). The velocity threshold for these features is lower than the threshold for simple unidirectional bulk flow stimuli used in previous studies. Thus, in addition to participating in the ensemble encoding of bulk air flow stimulus characteristics, the projecting GIs are also tuned to detect complex dynamical signal features that may correspond to important naturalistic stimuli such as approaching predators. Four main factors underlie the specialized feature sensitivity of these interneurons: (1) the specific characteristics of the distribution of mechanosensory hairs along the two cerci, (2) the operation of the cerci as delay lines for the sensory afferent inputs located at different distances out along the cerci (Mulder-Rosi et al. 2010), (3) the highly organized nature of the afferent terminal arborizations into a map of directional and dynamical stimulus parameters within the terminal abdominal ganglion, and (4) the architecture of the interneurons' dendritic branches within this afferent map.

Response Properties in Natural Condition

Most studies of the cercal sensory system GIs have been carried out in laboratory settings using carefully controlled stimuli. Using a piston mimicking the natural airflow of an approaching predator, Dupuy and colleagues recorded neural

activity of GIs through the abdominal connectives from the terminal abdominal ganglion of freely moving wood crickets (*Nemobius sylvestris*) in a semi-field situation (Dupuy et al. 2012). A cluster analysis of spike amplitudes revealed six different subsets of cercal interneurons. No spontaneous activity was recorded for the units of larger amplitude corresponding to the largest giant interneurons. Many of the smaller cercal units were already activated by background noise, sometimes only weakly, and the approach of a predator was signaled by an increase in their activity, in particular for the larger-amplitude units. A scaling law predicted that the cumulative number of spikes is a function of the velocity of the flow perceived at the rear of the cricket, including a multiplicative factor that increases linearly with piston velocity.

Chaos, Neural Population Models and

Thomas R. Knösche
Max Planck Institute for Human Cognitive and
Brain Sciences, Leipzig, Germany

Definition

Nonlinear dynamic systems, even if completely described by deterministic equations, may exhibit unpredictable behavior, in that arbitrarily small deviations in the initial conditions, after sufficient time has passed, lead to completely different behavior. This is referred to as deterministic chaos and has been shown to arise in neural population models (NPM).

Detailed Description

Chaotic Systems

Deterministic chaos occurs in systems completely described by deterministic differential equations. These systems may be quite simple, but they have to be nonlinear and live in phase spaces of at least three dimensions (Poincaré-Bendixson theorem). Chaos means that arbitrarily small differences in initial conditions nevertheless lead to strongly diverging trajectories of system behavior after some time. Consequently, under any realistic conditions the system's long-term behavior is unpredictable. In spite of the impossibility to predict the system's behavior in any single case, the chaotic dynamics are often not entirely arbitrary, but can be described by so-called strange attractors. Just like fixed points or limit cycles, strange attractors eventually attract all trajectories

that start within their basin of attraction. However, unlike those simple forms of attractors, strange attractors are not simply points or closed orbits, but form complex manifolds of fractal dimension in phase space. In spite of their spatial extent, they fill only an infinitesimally small fraction of the phase space. Examples are the Lorenz attractor (Lorenz 1963), which describes a simple hydrodynamic system, and the Rössler attractor (Rössler 1976), which was inspired by a taffy puller machine.

The rate with which nearby trajectories converge or diverge is described by the Lyapunov spectrum, comprising one Lyapunov exponent per phase space dimension (Politi 2013). If the largest Lyapunov exponent (LLE) is positive, the system is chaotic (in case of more than one positive Lyapunov exponent, one speaks of hyperchaos), while zero or negative LLEs indicate phase space contraction, that is, trajectories from a certain region in phase space tend to converge.

Whether or not a system is chaotic may depend on system parameters. The transition from deterministic to chaotic asymptotic behavior upon change of one or several system parameters is referred to as *route to chaos*. Very often this happens through an infinite succession of period-doubling bifurcations of decreasing spacing (Feigenbaum 1978). The chaotic region is usually interrupted by islands of stability in a fractal fashion.

Chaos in NPMs

In several types of NPMs, chaotic dynamic behaviors have been demonstrated. Freeman (1987) constructed an NPM of the olfactory system and demonstrated different chaotic regimes. More recently, Dafilis et al. (2001, 2009) investigated the parameter space for a cortical model of two neural populations, one excitatory and one inhibitory (Liley model). They showed that chaos can occur, when the excitatory input to the inhibitory population does not greatly exceed the excitatory input to the excitatory population. They also showed that chaotic and non-chaotic regions in parameter space form a complicated, apparently fractal, pattern. The time series and frequency

Chaos, Neural Population Models and,

Fig. 1 Largest Lyapunov exponent of a periodically driven Jansen-Rit model, as a function of stimulus amplitude and frequency. Positive exponents (magenta to black) reflect diverging trajectories and thus chaos. Zero exponents (white) indicate neutral stability, and negative exponents (cyan to yellow) reflect frequency locking. Several parameter regions with scattered, presumably fractal, patterns of chaotic regime are shown at a finer resolution. (From Spiegler et al. 2011)

spectra corresponding to the chaotic dynamics closely resembled real EEG in the gamma range (30–100 Hz).

Spiegler et al. (2011) investigated a periodically forced Jansen-Rit model and observed, when varying amplitude and frequency of the input, a complicated, presumably fractal, pattern of chaotic and non-chaotic regimes (Fig. 1). Interestingly, they showed that this pattern matches the estimated chaoticity (in terms of the LLE) of the time series of EEG under stimulation with light flicker of variable frequency.

Brain Dynamics: Stochastic Processes or Deterministic Chaos?

Time series of functional brain measurements, for example, electroencephalography or magnetoencephalography, feature a high degree of irregularity and unpredictability. There has been a discussion whether stochastic processes or deterministic chaos is the main reason for this behavior (Stam 2005). Both can clearly explain the observations in terms of time series and spectra. Stochastic elements in functional activity could originate from stochastic input from the outer and inner environments and from the very high number of relatively independent processes that

are present in the brain at any given time, while deterministic chaos can originate from the intrinsic dynamics of the neural circuits, as shown above. While stochasticity would be simply an epiphenomenon of brain function, chaos could play an important role in information processing (Skarda and Freeman 1987). Experimentally, chaos has been shown to exist at the single-cell level. There is, however, growing evidence for the existence of chaos at all levels of brain function and for its role as part of the neural code. For an extensive discussion, refer to Korn and Faure (2003).

Chloride Channels

Steven A. Prescott
Neurosciences and Mental Health, The Hospital for Sick Children, Toronto, ON, Canada
Department of Physiology, University of Toronto, Toronto, ON, Canada

Definition

Chloride channels play an important role in regulating neuronal excitability, especially in the

context of fast synaptic inhibition mediated by GABA_A and glycine receptors. But in order for chloride channels to reduce excitability, chloride driving force must be maintained via transporters that extrude chloride from the cell. Other transporters load chloride into the cell. The complicated and dynamic balancing of chloride influx and efflux, which also involves a variety of other ion species, directly affects how chloride channels regulate excitability.

Detailed Description

Function

Chloride ions participate in many cellular functions, from helping regulate cellular excitability to helping regulate cell volume. Those functions are mediated through a variety of chloride channels and transporters (Duran et al. 2010; Fig. 1). The regulation of neuronal excitability garners the most attention among neuroscientists. As the dominant charge carrier through GABA_A and glycine receptors, chloride is directly implicated in the efficacy of fast synaptic inhibition. Therefore, if chloride regulation is compromised, which occurs under a variety of pathological conditions including epilepsy and neuropathic pain (Kahle et al. 2008; Price et al. 2009), the efficacy of fast synaptic inhibition can be compromised with disastrous effects.

Understanding (and modeling) synaptic inhibition requires that we understand (and correctly account for) chloride flux. Synaptic inhibition is most often modeled as a simple current. But keeping in mind that chloride current reflects chloride flux and that chloride flux can sometimes deplete the chloride gradient, explicitly modeling chloride flux is sometimes necessary (Doyon et al. 2011).

Chloride Flux and the Electrochemical Gradient

The magnitude and direction of chloride flux across the cell membrane depends on the electrochemical chloride gradient. That gradient is described by the driving force, which is the difference between membrane potential and chloride reversal potential E_{Cl} . E_{Cl} is dictated by the ratio of intracellular and extracellular concentrations,

Chloride Channels, Fig. 1 Cartoon depicting membrane proteins that contribute to chloride flux. Channels (blue) let chloride move down its electrochemical gradient. Importantly, chloride can move in either direction through those channels depending on the direction of the gradient, notwithstanding rectification of the channel. The chloride

gradient is maintained by cotransporters (red) and exchangers (not shown) that harness the gradient of another ion species to move chloride against its gradient. Maintenance of the other ion gradients ultimately relies on the sodium-potassium pump (mauve). Numerous other proteins involved in chloride flux are not shown

$[Cl^-]_i$ and $[Cl^-]_o$, as explained by the Nernst equation. Under normal conditions (i.e., low $[Cl^-]_i$ and membrane potential between resting level and spike threshold), opening a chloride channel will allow chloride to flow down its electrochemical gradient and into the neuron. This influx represents an outward current since the direction of current is defined by the direction in which positive charge flows.

Notably, physiological conditions are often deliberately violated for the purpose of experimental testing. For example, in whole cell patch clamp recordings, high levels of chloride are sometimes included in the pipette solution (which will dialyze the cell) in order to increase the chloride driving force so as to improve the detection and measurement of chloride currents. Likewise, voltage can be clamped at values that, under normal conditions, would occur only briefly during a spike. Under these artificial conditions, chloride may flow in the direction opposite to what it would normally. To be clear, there is nothing wrong with such experiments, but one must consider the relevant factors when interpreting the results.

Chloride Transporters and Chloride Homeostasis

The ability of chloride to reduce excitability requires that chloride leak into the neuron. Passive movement of chloride down its gradient and into the cell would eventually deplete the chloride

gradient were it not for other mechanisms that serve to replenish the gradient by extruding chloride from the cell. (Notably, passive chloride flux can deplete the gradient, but it cannot reverse it, which is a topic we will return to later). The most important chloride extruder in central neurons is the potassium-chloride cotransporter KCC2 (Payne et al. 2003). KCC2 harnesses the potassium gradient such that chloride ions can piggy-back potassium ions out of the neuron through an electroneutral process (Fig. 1). Cotransport is not equivalent to pumping: Pumping is active (i.e., it depends directly on ATP hydrolysis), whereas cotransport is only secondarily active (i.e., it depends on ion gradients established and maintained by pumps).

The sodium-potassium-chloride cotransporter NKCC1 is also expressed in neurons and serves to load chloride into cells via the sodium gradient. In central neurons, KCC2 expression increases during development, whereas NKCC1 expression decreases (Ben-Ari et al. 2012). The same is not true for peripheral neurons, which is why GABA is depolarizing (although nonetheless inhibitory because of processes like sodium channel inactivation) in mature peripheral neurons.

Other proteins not depicted in Fig. 1 can also contribute to chloride homeostasis. These include sodium-dependent and sodium-independent anion exchangers. Exchangers, or antiporters, function like cotransporters in that they move one ion against its gradient by harnessing the

energy of a different gradient, but unlike cotransporters that move both ion species in the same direction, exchangers move each ion species in opposite directions.

It has also been suggested that certain rectifying leak channels, like ClC-2 , serve as one-way valves that selectively let chloride out of the cell. However, a passive leak process can only ever let chloride flow down its gradient, unlike cotransport, which moves chloride against its gradient by harnessing a different ion gradient. In short, the role of ClC-2 channels is context dependent, but they probably work in mature, healthy, central neurons to regulate excitability by leaking chloride into the cell. But to make this matter more confusing, certain members of the ClC family actually function as exchangers rather than as channels (Duran et al. 2010).

One should appreciate that there are other chloride channels not shown in Fig. 1. For instance, many neurons express chloride channels that are activated by increased intracellular calcium (Duran et al. 2010; Hartzell et al. 2005). Of particular clinical importance, the cystic fibrosis transmembrane conductance regulator (CFTR) is a chloride channel involved in regulating water flow across epithelia; mutations in this channel lead to, among other problems, dehydrated mucus that is excessively viscous and which therefore blocks ducts, leading to cystic fibrosis (Gadsby et al. 2006). Beyond their involvement in phasic synaptic transmission, GABA receptors can (depending on their subunit composition) be exquisitely sensitive to GABA, remaining open even in response to ambient levels of extracellular GABA and thus contributing a tonic chloride conductance to the cell (Lee and Maguire 2014; Sigel and Steinmann 2012). In all cases, channels rely on the passive movement of chloride down its electrochemical gradient.

Synaptic Inhibition and Chloride Flux

As already explained, synaptic inhibition by GABA_A receptors relies on chloride influx to produce an outward current. However, GABA_A receptors are often described as mediating shunting inhibition because they prevent the depolarization caused by concurrent excitatory

input rather than causing gross hyperpolarization. This occurs because the GABA reversal potential is close to the resting membrane potential, which means that chloride driving force is small, especially in the absence of a depolarizing event. Shunting inhibition works by GABA_A receptors mediating a chloride-based current that is proportional yet opposite in direction to the inward cation-based current mediated by AMPA/NMDA receptors. To be clear, cations entering via AMPA/NMDA receptors do not escape via the open GABA_A channels, contrary to what one might assume based on the term “shunting.” Consequently, even shunting inhibition involves chloride influx and, therefore, is not immune to the effects of chloride dysregulation.

Notably, GABA_A channels do not always mediate chloride influx. For example, in immature neurons and mature peripheral neurons that maintain a high intracellular chloride concentration through the actions of NKCC1 , GABA_A receptor activation leads to depolarization caused by chloride efflux. This is in contrast to the depolarizing GABA responses that occur in central neurons after pathological reduction of KCC2 and/or during sustained inhibitory input. Under conditions in which chloride extrusion capacity is reduced (but chloride is not actively loaded into the neuron, e.g., by NKCC1), chloride influx can rapidly deplete the chloride gradient, especially in small compartments like dendrites that have a high surface area-to-volume ratio (Doyon et al. 2011), but chloride flux does not reverse direction; instead, GABA-induced depolarization occurs because the associated bicarbonate efflux becomes dominant relative to chloride influx (Grover et al. 1993). The relative permeability of GABA_A channels to chloride versus bicarbonate is about 4:1 and should be accounted for by calculating the “GABA” reversal potential by using the Goldman-Hodgkin-Katz equation (which can accommodate multiple ion species) rather than the Nernst equation (which accommodates only one ion species). Because of the bicarbonate component, the functional reversal potential for GABA_A channels is usually several millivolts less negative than E_{Cl} .

Summary

Chloride plays a crucial role in helping regulate neuronal excitability, especially in the context of fast synaptic inhibition. Inhibition normally relies on chloride moving into the neuron, and inhibition may thus fail if chloride is allowed to accumulate intracellularly. Indeed, the direction and magnitude of chloride flux depend on the electrochemical chloride gradient, which in turn depends on the regulation of intracellular chloride levels. A variety of transporters work to regulate intracellular chloride levels, implicating other ion species in the process. This dynamic balancing of chloride influx and efflux is transparent under normal conditions, but the complex interplay between processes must be accounted for when any one of those processes goes awry.

Consumer behavior; Decision-making; Preference mapping.

Definition

The pattern of response allocation when making a selection among several choice alternatives.

Detailed Description

Choice behavior – the description of response allocation patterns when making a selection among several choice alternatives, as well as the identification of the choice-underlying psychological and neural mechanisms and their evolutionary origins – has been the topic of study in many scientific disciplines. Economics, mainly micro- and macroeconomics, has generated formal models of choice behavior that are designed to make accurate predictions of (aggregate) human behavior while making as few assumptions as possible and while being agnostic about the choice-underlying mental mechanisms. Psychologists are traditionally more concerned with describing and explaining the observable reality of human decision, but psychological theory is often also tested with animal models as approximations of specific, isolated aspects of human

behavior. Biologists are interested in choice behavior, too. Optimal foraging theory, for instance, prescribes and explains how animals should make optimal foraging decisions in variable environments if they were to maximize Darwinian fitness. Neuroscientists have started to reveal the neural mechanisms underlying choice behaviors in animal and human models. Thus, despite a superficially obvious dominance of economic theory in the study of human decision making, the science of choice behavior comprises many different approaches from different schools of thinking and applies to human as well as animal subjects. This entry is meant to give an overview of the different approaches to animal and human choice behavior.

Choice Behavior in Microeconomics: Revealed Preferences

In economic theory, choices, measured as the response distribution among a range of alternatives, are the observable behavioral output of a process that draws upon *preferences*. Preferences are unobservable cognitive structures specific to an individual in a particular context. It is usually assumed that a decision maker behaves *as if* he or she was maximizing a utility function. A utility

function is a mathematical construct linking objective quantities of a (single) good A to the subjective value (utility) it renders (Fig. 1a). This utility function is usually assumed to be concave and decelerating, meaning that the additional utility gained per unit of A decreases as a function of the amount of A already owned. For example, increasing the wealth of a very poor beggar by \$100 yields a very large additional utility to the beggar, whereas adding \$100 to the fortune of a very rich person yields little additional utility. The increase in utility as a function of goods already owned is called *marginal utility*. The *marginal utility function* (Fig. 1b), obtained by plotting the increase in utility due to receiving an additional unit of A, follows an exponential decay (Friedman and Savage 1948; Bernoulli 1954; Kahneman and Tversky 1979).

Preferences and utility functions are not visible, but can only be inferred from observable choices. In the analysis of consumer choice behavior, preferences are often inferred by pitting against each other two or more bundles, consisting typically of different quantities of good A and good B and observing the pattern of responses of the consumer. These choices or *revealed preferences* are thought to reflect the outcome of the consumer's internal decision-making processes and are an inherently *relative*

Choice Behavior, Fig. 1 Utility and marginal utility functions. (a) A utility function links objective quantities of a good with the subjective pleasure ("utility") derived from these goods. The concave, decelerating function

captures the notion that a small increase given a poor reference is more valuable than a similar small increase against a wealthy background. (b) Each additional unit of a good thus confers less additional or *marginal* utility

property. The consumer is assumed to maximize her/his *utility* (Von Neumann and Morgenstern 1944), or subjective pleasure, derived from obtaining each of the alternatives within her/his *budget* constraints. This is illustrated by plotting revealed preferences on a budget line diagram (Fig. 2). (Although the concept “*utility*” is often equated with subjective pleasure, this is an imprecise paraphrase of its historical meaning, since economic theory is agnostic about the actual mental mechanisms producing choice. Thus, strictly speaking, the term *utility* is inherently descriptive and does not refer to any actual hedonic or emotional states.) When asked to spend her/his budget between goods A and B within the allotted budget, the consumer reveals her/his preferences between A and B by selecting a certain bundle on the budget line. This bundle represents the best possible alternative available to the consumer within the budget. The weak axiom of revealed preferences (WARP; Samuelson 1938) states that the selected bundle is at least as good or better than other bundles on the budget line and strictly preferred over all other bundles that contain less goods

than the chosen bundle (every bundle inside the triangle). This prediction is derived from the assumption that, if the consumer prefers A over B, he or she cannot simultaneously prefer B over A and that more of a good thing is better than less of a good thing (cf. Glimcher 2010). WARP is an appealing theory with only minimal assumptions, but has little predictive power outside the revealed preference set. WARP has been extended to GARP, the generalized axiom of revealed preferences, refined, and shown to be a necessary and sufficient condition for choice data to be consistent with the maximization of a continuous, concave, and monotonic utility function (Houthakker 1950; Afriat 1967; Harbaugh et al. 2001). Satisfying GARP implies internally consistent decision making and transitivity, i.e., the preservation of a preference order, presumably corresponding to an at least ordinal utility ranking of the choice alternatives.

The chosen bundle is also informative about the consumer’s relative preference between A and B. More precisely, one could ask which bundles other than the chosen one would be equally valuable (i.e., render equal utility) to the consumer. Let us assume a consumer wanted to buy fruit and chose a bundle containing 4 apples and 3 oranges. And let us now assume that one apple is taken away from this bundle. How many oranges would we need to add to this new bundle to make it equally valuable to the old bundle? Removing one apple may be compensated by adding, say, one orange. However, the less apples the consumer has in his bundle, the more valuable each apple becomes (evident from the concave shape of utility functions), so if yet another apple is removed, one may have to add 2 additional oranges to make the next bundle equally attractive. Such equally valued bundles can be linked with an *indifference curve* (Fig. 2), a function that is convex to the origin, tangential to the originally chosen bundle, and represents combinations of good A and good B that render equal utility. The rate at which a consumer is willing to give up one unit of A in favor of one unit of B is called the *marginal rate of substitution* and can be read out from the slope of the indifference curve.

Choice Behavior, Fig. 2 Revealed preferences, the budget line, and indifference curve. If a consumer is asked to spend a budget of 10 units between good A and good B, both priced at 1 unit per good, her/his chosen bundle (purple circle on the blue budget line) reveals her/his preference. The indifference curve (red) links hypothetical bundles that would render equal utility to the chosen bundle. The marginal rate of substitution moves away from 1:1 as either good A or good B becomes scarcer and the utility attached to each unit of the scarce good increases

Choice Behavior in Animals: Optimal Foraging

It is very likely that evolution has shaped the way in which people make decisions. The evolution of decision making can be investigated by studying animal choice behavior. Biologists usually assume animals forage for food, choose mating partners, or make other decisions affecting their fitness. According to this view, natural selection has favored the development of specific choice behaviors that maximize the decision maker's Darwinian fitness, e.g., that optimize their energy intake and reproduction success (Kalenscher and van Wingerden 2011). Thus, like humans, animals encounter a plethora of choices in relation to food intake and energy expenditure. In the field of behavioral ecology, *optimal foraging theory* is a normative theory that prescribes that animals should make foraging decisions that maximize their *fitness*, operationalized as the ratio of food intake over expenditure to ensure survival (Charnov 1976) or reproductive success (Hamilton 1964a, b). When taking into account that a given food patch becomes depleted over time and obtaining additional energy intake therefore is associated with progressively larger amounts of energy spent foraging, the *marginal rate of energy intake* mirrors the shape of the marginal utility function. Indeed, animals are sensitive to the marginal rate of energy intake when making foraging decisions.

Choice Distribution: Herrnstein's Matching Law

When making repeated decisions between options A and B, a decision maker should consistently choose the option that represents the highest utility. Typically, however, this is not how animals behave in such a choice situation. Since the *reward rate* associated with a given option might change over time, it pays to switch between exploitation and exploration of choice options. The *matching law* (Herrnstein 1961) states that animals distribute their responses across choice options to match the relative rates of reward obtained from those options. So, for instance, if

option A provides three units of reward and option B provides one unit, then option A is typically chosen three times as often as B. Indeed, when given a choice, animals do explore the alternatives as predicted by the matching law (Kalenscher et al. 2003; Sugrue et al. 2004).

Choice Behavior Under Risk: Expected Utility

Often, the outcome associated with a choice option is not deterministic, but probabilistic. Probabilistic outcomes can be drawn from a distribution with known variance (such as a dice toss), in which case economists say that the outcomes are subject to *risk*. Thus, risk is often defined as outcome variance. Risk contrasts with *ambiguity*, which occurs when the variance in the outcome distribution is not (yet) known (Burke and Tobler 2011). In addition, uncertainty, defined as the inverse of predictability of the outcome, has been shown to affect decision making too. Risk, probability, and uncertainty are related concepts, as illustrated in the following example. Assume a decision maker chooses between the following gambles:

(A) Win \$90 or \$110 with equal probability ($p = 0.5$).

or

(B) Win \$50 or \$150 with equal probability ($p = 0.5$).

Both alternatives have equal expected value (the sum of the products of the probabilities times reward magnitudes is \$100 in both cases). However, alternative (B) has the higher outcome variance and is therefore the riskier alternative. For each alternative, the uncertainty of each outcome is maximal because $p = 0.5$. Changing the reward probabilities would skew the outcome distribution and would affect the alternatives' expected values. Uncertainty decreases towards the probability extremes and is zero at $p = 0$ or $p = 1$.

Risk also seems to play a role in animal foraging decisions. For example, the actual caloric

yield associated with hunting a certain type of prey varies depending on the specifics of the prey and the amount of energy spent during the hunt. A predator could opt for initiating a hunt subject to high risk with regard to the actual outcome or rather pursuing a low-risk foraging strategy with a tighter outcome distribution. In humans, risk and probabilities can be simultaneously or independently instructed, whereas animals typically have to sample the outcome distribution to arrive at estimates of outcome risk and probabilities (Schultz et al. 2008, 2011; Tobler et al. 2009; O'Neill and Schultz 2010).

The most prominent normatively flavored framework for understanding decision making under risk in humans is the *expected utility theory* (EUT; Von Neumann and Morgenstern 1944). EUT states that a decision maker should integrate the utilities of all possible outcomes of a decision weighted by their probabilities into an expected utility estimate, which can then be used to compare option alternatives. EUT proposes a set of mathematical equations to describe choice behavior based on four axioms that define a rational decision maker (rational in this case means that the decision maker exhibits stable preferences and behaves consistently with respect to them). These

axioms are completeness, continuity, transitivity, and independence. The first three prescribe that a decision maker can and will rank option alternatives consistently, while the fourth ensures that alternatives are evaluated independently, such that, for instance, the rank of an alternative should not be affected by the availability of an inferior alternative. If the axioms of EUT are met, option A should be preferred over option B if and only if $U(A) > U(B)$, that is, if the utility derived from option A exceeds that obtained from option B. If a consumer's choices imply a concave utility function, EUT predicts risk aversion if the choice is between a risky outcome (i.e., equiprobable low and high payouts) versus a safe outcome (certain, medium-sized outcome, Fig. 3). Due to the decreasing rate of marginal utility implied in concave utility functions, high outcomes are discounted more relative to small outcomes, so that

$$U_{\text{high}} + U_{\text{low}} < 2 * U_{\text{med}}$$

resulting in net risk aversion. In the study of foraging decisions, the concept of outcome variance has been captured in risk-sensitive foraging theory by assuming that energy intake is

Choice Behavior, Fig. 3 Risk aversion and risk proneness. Utility functions can explain risk attitude according to expected utility theory and risk sensitivity theory. (a) Utility (for humans) or Darwinian fitness (for animals) as a function of the magnitude of a commodity. The utility/fitness curve is concave and is a decelerating function of the current level of stimulus magnitude (wealth/amount) because the marginal utility/fitness increment decreases

with increasing level of stimulus magnitude. A concave utility/fitness function predicts risk aversion when choosing between a medium-sized, certain reward (R_M) and a risky option offering large or small rewards (R_S and R_L) with equal probabilities. (b) A convex function predicts risk proneness. (Taken from Kalenscher and van Wingerden (2011), with permission)

nonlinearly coupled to Darwinian fitness, resulting in a decreasing rate of marginal fitness that in turn predicts risk aversion (Kacelnik and Bateson 1996; Kacelnik 1997; Stephens 2008). Indeed, humans and animals are mostly risk averse in many domains and situations, although they occasionally exhibit risk-seeking behavior (Friedman and Savage 1948; McCoy and Platt 2005; Tobler et al. 2007; Glimcher 2008).

Choice Behavior with Delayed Outcomes: Discounted Utility

Besides outcome variance, delay to reward is another important factor affecting choice behavior. Humans and other animals, when given a choice between two equally sized but differentially delayed outcomes, will prefer the sooner reward to the later reward (Samuelson 1937; McDiarmid and Rilling 1965; Rachlin and Green 1972; Ainslie 1974; Kalenscher and van

Wingerden 2011). This process, called *delay discounting*, has been formalized in the normative economic framework of *discounted utility theory* (DUT; Samuelson 1937; Koopmans 1960; Prelec and Loewenstein 1991; Kalenscher and Pennartz 2008). DUT states that the value of a delayed reward decreases with the duration of the delay according to a discount function. Therefore, in maximizing the utility of her/his choices, a decision maker should take into account the *discounted utility*, derived by reducing the utility of each of the alternatives according to this time-dependent discount factor.

The shape of the discount function has been the subject of debate. Originally, a decreasing exponential with a constant discount factor was proposed (Samuelson 1937). An exponential discount function predicts that preferences are stationary, i.e., that the addition of a common delay to both alternatives in an intertemporal choice task should not interfere with the preference order (Fig. 4a; Koopmans 1960). Formally

Choice Behavior, Fig. 4 Constant vs. hyperbolic discounting. Constant vs. hyperbolic discounting of future events. The figure describes a choice between a small, short-term outcome or a large, long-term outcome (proximal) and another situation in which both outcomes are deferred into the future by the same time interval (distant). (a) Constant (here: exponential) utility function of a large, delayed (gray line) and small, short-term commodity (black line). With exponential discounting, preference stationarity holds when the rewards are deferred by the same time interval into the future. (b) People seem to

place a premium on short-term availability of rewards, deflecting the discount into an upward direction for temporally close rewards. The resulting hyperbolic discount function can explain preference reversals over time. Due to the steeper utility decay for short delays, the utility of the small, short-term commodity is higher than that of the large, delayed reward for temporally proximal outcomes, but the utility order reverses when both outcomes are deferred into the future. (Taken from Kalenscher and Pennartz (2008), with permission)

put, if a decision maker is indifferent between option A delivered at time t_1 and option B delivered at time $t_1 + \Delta t$, that is, choosing both options about 50% of the time, then preference stationarity states that he or she should also be indifferent between option A delivered at a later time t_2 and option B delivered at $t_2 + \Delta t$ (Eq. 1):

$$\text{If } A(t_1)\tilde{B}(t_1 + \Delta t) \text{ then } A(t_2)\tilde{B}(t_2 + \Delta t) \quad (1)$$

However, empirical evidence shows that in many situations, decision makers exhibit *time-inconsistent preferences* (see ► “Decision-Making, Bias”). This means that a decision maker prefers $A(t_1)$ over $B(t_1 + \Delta t)$ but $B(t_2 + \Delta t)$ over $A(t_2)$ after the addition of some common delay $t_2 - t_1$ (Ainslie 1975; Green et al. 1994; McClure et al. 2004). Given this evidence, a hyperbolic discount function, which can explain preference reversals after adding common delays, has been proposed (Fig. 4b; Ainslie 1975; Mazur 1984, 1988; Rachlin et al. 1991; Green et al. 2010). The tendency of humans and other animals to put a premium on the short-term availability of rewards has been called *impulsivity* or *failure of self-control* (see ► “Decision-Making, Bias”).

Ecological Rationality: Sequential Background-Foreground Choices

It has been argued that the (binary) choice between two differentially delayed alternatives is an artificial testing situation that does not correspond to the contexts in which animals make, and arguably preindustrial age humans made, their decisions. Stephens (2008) and coworkers have emphasized the use of sequential choice paradigms to approach foraging behavior, using *patches* as canonical units of foraging. A patch constitutes a finite-sized resource that can be exploited more than once. Importantly, the marginal rate of return decreases with each subsequent extraction until the patch is depleted. The foraging animal thus faces a sequential stream of choices to either stay and further exploit the patch or go and explore another source, which likely

depends on parameters such as the current rate of return given the patch depletion state and the travel time to the next patch. This type of sequential choice has a background-foreground structure in which the forager default or *background strategy* is to explore the environment for food, which can be temporarily put on hold to follow the *foreground strategy* of exploiting the current foraging options, such as gathering additional nectar or attacking a prey. Stephens et al. model intertemporal choice behavior using a patch paradigm by splitting the large, delayed reward in two smaller rewards. After receiving an initial small reward, the animal can choose to stay for an additional delay, resulting in the delivery of the second reward, or go and start a new trial (Fig. 5).

Self-control paradigm

Patch-use paradigm

Choice Behavior, Fig. 5 Self-control and patch-foraging paradigms. Two “equivalent” decision contexts. In the self-control paradigm, the subject makes a binary choice between a small immediate outcome (G_1 after t_1) and a large delayed outcome (G_2 after t_2). In the patch paradigm, the forager’s choice has equivalent consequences, but the forager decides whether to stay in the patch and collect $G_2 - G_1$ additional units of food after $t_2 - t_1$ or to leave immediately after obtaining the small amount G_1 . In the latter, but not the former case, the inter-trial interval (τ) is part of a key delay to the next reward opportunity. (Taken from Stephens and Anderson (2001))

By adjusting the time delays in the patch preparation to the delays typically used in the self-control or intertemporal choice paradigm, the mean outcome rates over time associated with the choice options can be matched precisely (Stephens and Anderson 2001). Whereas animals typically make many “impulsive” decisions in the binary intertemporal choice paradigm, resulting in a sub-optimal rate of energy intake, they attain much higher energy intake rates in the economically equivalent patch paradigms. Modeling choice behavior through decision rules, Stephens and Anderson show that the identical “shortsighted” decision rules produce optimal choices, in the sense of maximizing energy intake rates over time, in one paradigm (the patch situation), but very clearly not in the other paradigm (the binary intertemporal choice situation). Specifically, in the patch paradigm, the inter-trial interval becomes a key delay, included in the stay/leave decision, so that the short-term and long-term optimality of the choice for the larger, delayed reward becomes aligned (see ► [“Decision-Making, Bias”](#)).

Neural Correlates of Choice Behavior

Economic theory is traditionally agnostic regarding the mental mechanisms underlying choice behavior, but is only concerned with accurately describing and predicting choices. As a consequence, a common notion in economics is that a decision maker behaves “as if” he or she was maximizing a utility function, but economic theory does not assume that there actually is such a thing as a mental representation of a utility function. Recently, this agnostic view has been challenged by advances in the neurosciences aimed at investigating whether there actually is a neural representation of (cardinal) utility in the brain. This new “neuroeconomics” paradigm (Glimcher and Rustichini 2004) has proven quite fruitful in finding correlates of inferred utilities and, conversely, in predicting choice from neural data, supporting the validity of an underlying utility function guiding choice behavior.

The neural correlates of value-based decision making (as distinct from, e.g., perceptual decision

making or categorization) have been investigated in both humans and animals. A well-established finding in the research on value coding in the brain is that frontal brain regions such as the orbitofrontal cortex (OFC), lateral prefrontal cortex (IPFC), ventromedial prefrontal cortex (vmPFC), and anterior cingulate cortex (ACC) show differential levels of activity with regard to the (expected) value of a stimulus (see recent reviews by Rangel and Hare 2010; Louie and Glimcher 2012). Though the values associated with stimuli and actions influence neural processing in many other cortical and subcortical brain regions, electrophysiological recordings made from primate OFC (area 11/13, which has homologues in rodents and humans; Wallis 2012) indicate that neural representations of value associated with outcomes found in that brain region are independent of the action required to obtain the said outcome, its physical location, and, to some degree, its sensory features (Padoa-Schioppa and Assad 2006, 2008; Padoa-Schioppa 2007). When monkeys were faced with a binary choice, some neurons showed variation in firing rate that correlated with the derived subjective utility estimate of the chosen alternative, called *chosen value* correlates. Such an abstract representation of subjective value in a *goods-based model* (Padoa-Schioppa 2011) of choice alternatives approximates economic value as defined in normative frameworks such as EUT or DUT (see above). In humans, similar representations of expected and obtained value, which could inform decision-making processes and decision evaluation, are present in the ventromedial prefrontal cortex (Kable and Glimcher 2007, 2009; Kahnt et al. 2010) and ventral striatum (Knutson et al. 2001; Tobler et al. 2007; Rolls et al. 2008; Christopoulos et al. 2009).

Neural Coding of Risk, Probability, and Delays Associated with Outcomes

As outlined above, risk/outcome variance, probability/uncertainty, and delay to reward all influence choice behavior. Assuming that revealed preferences reflect internal decision-making

processes using the ordinal utility ranking of choice alternatives and that these processes rely on cardinal representations of value in the brain, it follows that neural signals in some brain areas should be sensitive to these parameters (Burke and Tobler 2011).

Risk

In humans, signals of risk, defined as outcome variance or reward volatility, can be found as BOLD activity correlates in the anterior cingulate cortex (Behrens et al. 2007; Christopoulos et al. 2009), OFC (Tobler et al. 2007), and VStr (Kuhnen and Knutson 2005). In nonhuman primates, a population of neurons recorded from macaque OFC and posterior cingulate cortex (CGp) show firing rates that correlate with risk levels. When given a choice between safe and risky outcomes, under certain conditions, these animals prefer the risky outcome, with their preference increasing as the risk increases (McCoy and Platt 2005; O'Neill and Schultz 2010); however, this risk-seeking behavior is linked to the objective levels of reward, so it reverses to risk-neutral or risk-averse behavior when higher outcomes are at stake. In macaques, these neuronal risk signals occur separately from expected value signals present in other OFC neurons, but in rats, risk does modulate reward-related neuronal responses (Roitman and Roitman 2010). Dopamine neurons also code a tonic risk signal in the delay interval between stimulus and outcome (Fiorillo et al. 2003, 2005; Tobler et al. 2005). It thus appears that the brain maintains an isolated measure of outcome variance, tracking the volatility of the reward environment. From an efficient coding perspective, this measure of risk should influence the neuronal representation of outcomes by scaling these representations to their mean (expected outcome) and variance (risk) to facilitate reward discrimination (Schultz et al. 2011; Louie and Glimcher 2012). Recordings of neural activity in primate and human OFC and primate lateral intraparietal area (LIP) show that this is indeed the case (Elliott et al. 2008; Padoa-Schioppa 2009; Louie et al. 2011; Louie and Glimcher 2012).

The neural basis of risk attitudes has recently been investigated, indicating that value signals related to risky outcomes in lateral prefrontal

cortex are modulated by individual risk attitudes (Tobler et al. 2009). The value signal of risky options was attenuated by increasing risk in risk-averse participants, but increased in risk-seeking participants. In addition, anticipation of risk differentially modulated neuronal activity in ventral striatum (VStr) and anterior insula (AI) for risk seekers and risk avoiders (Rudorf et al. 2012).

Probability

While a neural correlate of risk associated with a certain stimulus is informative for tracking the volatility of the expected outcome stream, a stimulus that predicts reward with $p = 0.75$ should clearly be valued higher than a stimulus that predicts reward with $p = 0.25$, in spite of equal risk associated with both stimuli. In contrast to humans, who can be instructed on probabilities, animals have to experience the outcome distribution. As probabilities associated with stimuli become known through repeated sampling, neural signals of outcome probabilities could emerge. Platt and Glimcher (1999) presented monkeys with pairs of stimuli that differed in the probability of associated reward, while recording the activity from neurons in LIP. They found that LIP neurons coded the action (a saccade) required to obtain the reward and that these neuron's firing rates were modified by both the probability of receiving a reward and its magnitude. When the probability of reward varied, animals exhibited matching behavior (see above), mirrored by neural activity in LIP that tracked the expected reward associated with each saccade target across trials (Sugrue et al. 2004). Dopamine neurons in the ventral tegmental area (VTA) of macaques also seem to incorporate probability in coding an expected outcome signal at the time of stimulus onset, in line with EUT (Fiorillo et al. 2003). In rats, neural activity in OFC single cells and ensembles discriminates between different probabilities (Van Duuren et al. 2009). In monkeys, firing rate modulation by outcome probability was found in ACC, OFC, and lateral prefrontal cortex by Kennerley et al. (2009) and Wallis and Kennerley (2011). Interestingly, the OFC contained a larger proportion of neurons that seemed to code an isolated probability signal, whereas this parameter was more

often integrated with other decision parameters in ACC and IPFC.

Delay

Humans and other animals prefer immediate over delayed rewards (see above). One view on the neural basis of these time preferences holds that immediate and delayed rewards are actually processed by different neural systems that compete for behavioral control. The so-called β system is placed in the mesolimbic reward areas such as VStr and OFC and is thought to process the immediate value of reward, while the δ system, located in prefrontal and parietal regions, performs basic exponential discounting of delayed rewards (McClure et al. 2004, 2007). Together, the β/δ system combines into a hyperbolic-like discounting function consistent with theoretical and experimental data (Ainslie 1975; Mazur 1984, 1988; Rachlin et al. 1991) with more steep discounting in the β than the δ network. Although the view that discounting is the consequence of two separate neural choice systems has been criticized (Kable and Glimcher 2007), recent models posit that the discounted future reward value is neutrally represented as a singular signal in ventromedial prefrontal cortex which, however, can be modified by activity in brain structures that were associated with the δ system, mainly dorso-lateral prefrontal cortex (Hare et al. 2009; Figner et al. 2010). In primates, single neurons in LIP (Louie and Glimcher 2010), OFC (Roesch and Olson 2005), and striatum (Cai et al. 2011) encode subjective value modulated by delay to reward. Likewise, single-neuron activity in the PFC homologue of pigeons (Kalenscher et al. 2005) and in rat OFC (Roesch et al. 2006) and other limbic structures (reviewed in Roesch and Bryden 2011) is sensitive to delay. However, in pigeons, the reward signal integrates delay to reward with magnitude, whereas this is not the case in rat OFC, amygdala, and ventral striatum.

The importance of the OFC for the representation to delayed rewards is underlined by the numerous lesion studies that have implicated this region, sometimes with opposing effects (Mobini et al. 2002; Winstanley et al. 2004; Rudebeck et al. 2006; Mar et al. 2011). In rats, Mar et al.

found that the exact anatomical locus of the lesion differentially affected delay discounting, with lateral OFC lesions increasing and more medial lesion decreasing discounting, respectively.

Neural Representation of Value in Foraging

As reviewed earlier, the binary choice context presented in most of the studies discussed above might not reflect the choices for which neural processes have presumably been adapted in the course of evolution (Stephens 2008; Kalenscher and van Wingerden 2011). If choice behavior relies partly on evolutionarily old adaptations to the stay/leave decisions made during foraging, it follows that the relative value of these alternatives should be represented, perhaps separately, in phylogenetically older brain structures. The challenge in foraging can be conceptualized as calculating the relative outcome rate of the current foreground environment versus the mean outcome rate of the background. Recent work in humans and primates indicates that dorsal ACC seems to code signals that relate to stay/go decisions in patch-foraging paradigms (Hayden et al. 2011; Kolling et al. 2012). While the OFC/vmPFC seems mainly concerned with current or chosen value, dACC activity scales with the relative level of reward in the background in both humans and macaques, possibly serving as a reference estimate for stay/leave foraging decisions.

Definition

An algorithmic description of how deflections of the stereocilia in an auditory sensory receptor cell, or cochlear inner hair cell, cause fluctuations in the cell's intracellular voltage or receptor potential.

Detailed Description

Cochlear inner hair cells (IHCs) are auditory sensory receptor cells located in the organ of Corti. They have stereocilia that deflect following mechanical motion of the organ of Corti (Fig. 1). The fluid surrounding the stereocilia bundle, the endolymph, has a positive electrical potential (80–120 mV), while the electrical potential within the IHC is negative at rest (around –60 mV). Stereocilia deflection toward the tallest cilium in the bundle increases the inward flow of positive ions, mostly potassium (K^+), and thus increases the cell's intracellular potential. This mechanism effectively transduces a mechanical signal (stereocilia motion) into an electrical signal (the IHC intracellular or receptor potential). This mechanism is important because the IHC receptor potential controls the influx of calcium ions (Ca^{2+}) through voltage-gated channels, and intracellular calcium triggers the release of neurotransmitter from within IHC to the synaptic cleft, which then triggers action potentials in nearby auditory nerve terminals.

Increasing the amount of stereocilia deflection increases the proportion of open transducer channels and the magnitude of the receptor potential. The rate of increase is nonlinear due to two mechanisms: the saturation of transducer current (Lukashkin and Russell 1998) and the outward flow of K^+ through the IHC basolateral membrane (Kros and Crawford 1990). While stereocilia deflection in one direction increases the receptor potential, deflection in the opposite direction closes transducer ion channels and prevents the inward flow of K^+ ions to the cell. This asymmetric and saturating gating of transducer channels explains why the receptor potential shows an AC and a DC component. It also

Cochlear Inner Hair Cell, Model, Fig. 1 An inner hair cell and its equivalent electrical circuit model. Stereocilia deflection toward the tallest cilium increases the inward flow of K^+ , which increases the cell's intracellular potential (V). In the model, this is described by a conductance (g_A) in the apical portion of the cell's membrane, which is typically assumed to be the sum of a mechanically sensitive K^+ conductance and leakage conductance (not shown). The "excess" of intracellular K^+ is reduced by an outward K^+ current through voltage-gated basolateral channels. In the model, this is described by fast-activating ($g_{K,f}$) and slow-activating ($g_{K,s}$) basolateral K^+ conductances. The cell's intracellular voltage (V) controls the inward flow of calcium (Ca^{2+}), which controls the release of neurotransmitter vesicles from within the cell. The intracellular voltage also depends on other parameters: E_t endocochlear potential; R_t , R_p epithelium resistances; C_A , C_B capacitance of the apical and basal portions of the cell's membrane, respectively; $E_{K,f}$ and $E_{K,s}$ reversal potentials of the fast and slow basolateral K^+ currents, respectively. (Model adapted from Lopez-Poveda and Eustaquio-Martin 2006)

explains why the IHC is said to operate as a saturating, half-wave rectifier.

The IHC receptor potential is also determined by the resistor-capacitor effect of the IHC membrane and by the homeostasis of the organ of Corti. The amplitude ratio between the AC and

DC receptor potential components decreases with increasing stimulus frequency (Russell and Sellick 1978), which explains the common notion that the IHC operates as a low-pass filter. Less acknowledged, however, is that the AC receptor potential alone shows a band-pass response tuned at a frequency around 500 Hz (Sellick and Russell 1980) or 1 kHz (Dallos 1985) for low stimulus intensities. The rising slope of the AC frequency response probably results from receptor potential responding to the velocity of vibration of the organ of Corti for frequencies below approximately 200–500 Hz and to its displacement above that frequency (Sellick and Russell 1980).

The IHC responds nonlinearly also in time. The time-dependent activation of basolateral K^+ channels induces nonlinear, time-dependent adaptation of the receptor potential which could contribute partly to auditory nerve adaptation (Kros and Crawford 1990; Kros 1996).

Approaches to Model the IHC Transfer Function

IHC models aim at simulating the cell's receptor potential in response to a time-varying signal describing stereocilia motion. Traditionally, the IHC transfer function has been modeled using biophysical analogs and signal-processing analogs, as reviewed elsewhere (Meddis and Lopez-Poveda 2010).

Signal-processing models consider the IHC as a cascade of an asymmetric, saturating, nonlinear gain, which accounts for the growth of the transducer current with increasing stereocilia motion, followed by a low-pass filter, which accounts for the resistor-capacitor filtering of the IHC membrane. The order and cutoff frequency of this filter are chosen so as to mimic as closely as possible the physiological low-pass characteristics of the IHC. These models are easy to implement and fast to evaluate and require very few parameters. They, however, neglect important aspects of IHC processing and are limited in scope. For instance, they disregard the voltage and time dependence of activation of basolateral K^+ currents that could be significant for hearing brief and intense sounds

(Kros 1996). Another shortcoming of these models is that their parameters do not represent physiological variables; hence, these models may be inappropriate to model hearing impairment associated with IHC dysfunction.

Biophysical IHC models are electrical circuit analogs of the full organ of Corti (an early review is given by Mountain and Hubbard 1996). Figure 1 illustrates an example model of this type by Lopez-Poveda and Eustaquio-Martin (2006). It consists of several elements that describe the electrical properties of the apical and basal portions of the IHC and its surrounding fluids. It is assumed that the IHC intracellular space is equipotential and thus can be represented by a single node (V). It is also assumed that the IHC intracellular potential is primarily controlled by the interplay of a transducer, variable (inward) K^+ current that results from stereocilia deflections, and a basolateral (outward) K^+ current that eliminates the excess of intracellular K^+ from within the IHC. The magnitude of the transducer current is calculated from stereocilia displacement using a Boltzmann function that describes the gating of transducer channels. The excess of intracellular K^+ is eliminated through two basolateral voltage- and time-dependent nonlinear activating conductances: one ($g_{K,f}$) with fast and one ($g_{K,s}$) with slow-activation kinetics. The activation of these two conductances is modeled using a Hodgkin-Huxley approach. The reversal potential of each of the currents involved is accounted for by a shunt battery ($E_{K,s}$ and $E_{K,f}$). The capacitive effects of the IHC membrane are modeled with a single capacitor ($C_A + C_B$). The receptor potential also depends on the endocochlear potential (E_t), which is simulated with a battery. The values of the model parameters are typically set to physiological values or are optimized to reproduce physiological data. This relatively simple electrical circuit accounts for a wide range of well-reported in vitro and in vivo IHC response characteristics (Lopez-Poveda and Eustaquio-Martin 2006).

There exist simpler biophysical models that consider voltage- and time-independent basolateral K^+ currents (Shamma et al. 1986). There also exist more sophisticated models that incorporate the role of transmembrane chloride

and sodium currents and pumps in shaping the IHC intracellular potential (Zeddies and Siegel 2004).

Applications

Both signal-processing and biophysical IHC models have been used successfully in composite models of the peripheral auditory system and related applications (reviewed by Meddis et al. 2010). In this case, it is typically assumed that the input to the IHC model is basilar membrane motion rather than stereocilia motion, and a high-pass filter is used to couple between the two (Shamma et al. 1986). This high-pass filter is important to mimic the abovementioned band-pass behavior of the AC receptor potential, which could be significant for low-frequency hearing (Lopez-Poveda et al. 2007). Recent evidence suggests that the motion of the reticular lamina would be a more accurate mechanical input to the IHC than basilar membrane motion (Guinan 2012).

Coexistence of Bursting Regimes

Robert Butera

School of Electrical and Computer Engineering,
Laboratory for Neuroengineering, Georgia
Institute of Technology, Atlanta, GA, USA

Definition

Coexisting bursting solutions are exhibited in some models of bursting (link) neurons. Such solution regimes manifest themselves as a large number (typically three or more) coexisting stable periodic solutions. These solutions coexist at a given fixed parameter set, persist indefinitely, and can be switched by between external perturbations.

Detailed Description

Overview

Many biological dynamical systems exhibit multistability. Such systems have two or more stable attractors for a fixed set of parameters. Multistable periodic systems exhibit two or more oscillatory attractors for a fixed set of parameters. Examples of multistability can be found in vertebrate motoneurons (e.g., Hounsgaard and Kiehn 1989, where two distinct spike firing rates of action potentials coexist), invertebrate neurons (e.g., Lechner et al. 1996, coexisting bursting and spiking oscillations), and small networks of coupled neurons (e.g., Kleinfeld et al. 1990). Outside of neuroscience, such multistable oscillations can be found in models of intracellular calcium oscillations (Haberichter et al. 2001) and coupled genetic oscillators (Koseska et al. 2007).

Bursting pacemaker neurons are single neuron oscillators with a unique oscillatory state – they alternate between an active episode comprised of a series of two or more action potentials and a silent phase characterized by a lack of the firing of action potentials. Such oscillations are autonomous and exhibited by neurons in a variety of neural systems. These include invertebrate neurons (Kandel 1979),

cortical neurons (Chagnac-Amitai and Connors 1989), and brainstem neurons (Smith et al. 1991). Such properties are considered to be common to neurons involved in either central pattern generation or neurosecretory functions.

Bursting neurons can have multiple stable solutions. The most common and simplest case is coexistence of silent, bursting, and/or periodic spiking solutions. The coexistence of two such states is often referred to as bistability. Coexistence of periodic spiking and bursting solutions has been suggested in computational (Butera et al. 1995) and experimental (Lechner et al. 1996) studies of Aplysia neuron R15. Bursting neurons are often described as having their dynamics on two distinct time scales, one fast, underlying the firing of action potentials, and one slow, underlying the slow dynamics. The slower dynamics of a bursting system are often studied in the lower-dimensional space of the slower state variables (e.g., Butera et al. 1997).

Canavier et al. (1993) have shown for the first time that a modeled bursting neuron can exhibit a large number of stable coexisting bursting solutions. These solutions all exist at the same fixed parameter set. The occurrence of a given solution is dependent on the choice of initial conditions, and an appropriate well-timed single perturbation can switch the oscillation from one stable solution to another. Simulated neuromodulators can alter the number of stable attractors (Canavier et al. 1994). Two unique properties are exhibited by these solutions. First, the distinct bursting oscillations are *concentric* when viewed in the state space of the slow variables. Second, each distinct bursting oscillation *has a distinct number of action potentials per cycle*. Some of the stable bursting solutions were limit cycles, while others were chaotic attractors. Appropriately timed transient inputs are capable of switching the trajectory from one attractor to the other, but otherwise the attractors are stable, as well as robust to a modest amount of noise.

Necessary Components

This phenomena was further investigated in a reduced 4-variable ion-channel-based model (Butera 1998), and necessary components were identified that give rise to multistability. These

assumptions were validated in a simplified 3-variable model. Further studies (Newman and Butera 2010) generalized the 3-variable model to one that is scalable to an arbitrarily large number of stable solutions and demonstrated experimental responses of bursting neuron R15 to transient input that are consistent with these mechanisms. Several key components underlie these solutions in all computational models studied:

1. The solution trajectory, during the silent phase of the burst, converges to a low-dimensional manifold (two dimensional in the examples studied).
2. A first-return map constructed on this manifold possesses a series of discontinuous solutions, with each continuous set corresponding to all solution trajectories with the same number of action potentials.
3. The first-return map can be decomposed into two distinct maps – a contractile map corresponding to the silent phase of the burst on the low-dimensional manifold and an expansive map which is discontinuous, with each distinct set of points corresponding to bursts with the same number of action potentials.

Computational Example

Figure 1 illustrates an example of a multistable bursting model. The model consists of two slow variables u_1 and u_2 and a quadratic integrate-and-fire-type model for the membrane potential variable v . At this parameter set (identical to those used in Fig. 2 of Newman and Butera 2010), three coexisting bursting solutions exist. Panel A illustrates the (u_1, u_2) phase space of the three solutions, all of which are stable limit cycles. The trajectories wind counterclockwise. When u_1 is at a sufficiently high value, the model starts firing action potentials, and with each firing of an action potential, the slow variables u_1 and u_2 are discretely perturbed. Panel B illustrates the time course of the three limit cycle solutions plotting v versus time. The solutions in panel B are color coded to correspond to the three phase-plane solution projections in panel A.

The dynamics of such a model can be studied by choosing a Poincare section (LINK) that spans

Coexistence of Bursting Regimes, Fig. 1 Multistability in a minimal bursting model. Model is from Newman and Butera (2010), with parameters identical to those used in Fig. 2 of that paper. (a) Phase-plane projection of the two slow variables of the model for

the three stable limit cycle solutions that coexist. (b) Plot of voltage versus time for the three stable limit cycle solutions, color coded to link to the identical solution trajectories in panel (a)

Coexistence of Bursting Regimes, Fig. 2 Mappings for understanding multistability in bursting models. (a) First-return map calculated by choosing initial conditions corresponding to positive y values on the Section S in Fig. 1. This is the mapping $y_1 \rightarrow y_3$, indicated by the example trajectory in Fig. 1. (b) Decomposed first-return map. The dotted line represents the mapping of all points y_1

to the corresponding crossing of S indicated by y_2 on Fig. 1. The dots represent the mapping of all points y_2 to the second cross of S indicated by y_3 on Fig. 1. This map is inverted so that both maps share y_2 on the y -axis. The color coding associates these maps with the solution trajectories in Fig. 1 that have the same number of action potentials as all the trajectories in these maps

all possible trajectories during the silent phase of the burst cycle. One such section is chosen and indicated by the line labeled S in Fig. 1. Initial conditions on this section y_1 are systematically chosen, and subsequent crossings of the section

in positive (y_2) and negative (y_3) direction are recorded. Using such an approach, a return map can be constructed. Figure 2a plots a return map of initial conditions along Section S in Fig. 1, plotting y_3 versus y_1 . Note the discontinuous nature of

the maps – each continuous family of solutions corresponds to all trajectories with the same number of action potentials during a burst. The data points corresponding to the same number of action potentials as the limit cycle solutions in Fig. 1 are colored accordingly.

To understand how the fast and slow processes interplay, the map can be decomposed into two separate maps. The map of $y_1 \rightarrow y_2$ represents the silent phase of the burst. This map is continuous, since action potentials do not fire, and is plotted by the dotted line in Fig. 2b. The map of $y_2 \rightarrow y_3$ highlights the effect of the action potentials in breaking up the map into discontinuous regions based on the number of action potentials fired. This is also plotted in Fig. 2b, only inverted, so that both maps share y_2 on the y-axis of the map. The intersection of these two maps is identical to the fixed points in the first-return map of panel A. By studying the effects of parameters on these maps, one can deduce how various components of the model contribute to modulating the map into having fewer or additional intersections, controlling the amount of multistability in the system.

Implications

The experimental validation of such models is challenging, as neurons exist not in isolation, but in complex networks. Newman and Butera (2010) illustrated experimental responses from bursting neuron R15 whose dynamics in response to transient inputs are consistent with the dynamics described by this class of models. They further postulate that this class of multistability can exist in a large number of bursting neuron models with circle/circle dynamics (Izhikevich 2007) and that even if only one attractor exists, such topology can give rise to complex transient responses to transient input.

While speculative, this type of bursting could underlie a form of memory not dependent on a slow time-scale process, but rather inherent in the stability of the attractors. Canavier et al. (1994) showed how neuromodulators could alter the number and stability of the attractors.

The feasibility of this idea has also been demonstrated in analog circuit implementations of these dynamics (Butera et al. 2002). Other dynamical

systems that exhibit such large-scale multistability typically rely upon the role of delayed feedback and have been demonstrated in neural systems (Foss et al. 1996) and engineered optical (Aida and Davis 1991) and digital (Aida et al. 1994) systems.

Definition

Coexistence of pathological and functional neuronal regimes designates a situation for the neural networks, where at least two regimes of the brain dynamics coexist related to either normal physiological (healthy) functioning or a pathological state. In other words, the corresponding neural populations demonstrate multistability of healthy and pathological attractors. Among pathological brain regimes one can distinguish several cases resulting in a number of neurological disorders

like epilepsy, Parkinson's disease, tinnitus, paroxysmal attacks of pain and muscle spasms, and bipolar disorders (Baldissera et al. 1991; Milton and Jung 2003; Foffani et al. 2003; Hammond et al. 2007; Roberts et al. 2010; Coggan et al. 2011; Goldbeter 2011; Raoul et al. 2012; Cloutier et al. 2012). Also, for the physiological regimes, several different attractors may coexist as found, for example, for multistable visual perception, central pattern generators in the context of motor control, resting states of the brain, memory and cognitive processes, etc. (Schöner et al. 1990; van Emmerik and Wagenaar 1996; Leopold and Logothetis 1999; Moreno-Bote et al. 2007; Briggman and Kristan 2008; Haken 2008; Sterzer et al. 2009; Deco et al. 2009; Lewis et al. 2009; Braun and Mattia 2010; Freyer et al. 2011). Multistability of pathological and functional regimes is by no means restricted to brain dynamics. Rather, both scientifically and clinically relevant multistability-related concepts are found in the field cardiac physiology. In fact, cardiac tissue supports several coexisting spatio-temporal dynamical patterns which can possibly be involved in the transition from reentrant tachycardia to fibrillation (Glass 2005; Hwang et al. 2005). The basis of such a complex phenomenon as multistability is a highly nonlinear character of the corresponding real systems, which implies the development and utilization of sophisticated modeling approaches and extensive computational and theoretical investigations.

Detailed Description

Introduction

A simple case of multistability, where two stable states coexist (bistability), is schematically illustrated in Fig. 1 (Hale and Kocak 1991; Strogatz 1994; Kuznetsov 1998; Thompson and Stewart 2002). If the system state is represented as a ball rolling in an energy landscape, then the latter may have the form of a double-well potential, see Fig. 1a. Two minima *A* and *B* stand for coexisting attractors which are separated by an unstable state *C*. The ball will approach one of the attractors if it is placed in the corresponding basin of attraction,

Coexistence of Pathological and Functional Neuronal Regimes, Fig. 1 Schematic illustration of bistability. (a) Energy landscape in the form of a double-well potential, where the system state is represented by a rolling ball. (b) Possible evolution of the potential when a selected parameter varies. (c) One-parameter bifurcation diagram where the stable and unstable states are depicted by black solid and dashed curves, respectively. Bistability emerges for parameter $p \in (p_1, p_2)$, and the red curves show a hysteresis when the parameter changes in the directions indicated by arrows

which reflects an appropriate choice of the initial conditions. If system parameters vary, the potential may undergo transformations, for example, one of the attractors may lose its stability or disappear (Fig. 1b). Such transitions, called bifurcations, can be illustrated by a one-parameter bifurcation diagram, when the limit system states are plotted versus the bifurcation parameter, see Fig. 1c. For parameter $p < p_1$ or $p > p_2$ the system is monostable and only one attractor exists, A or B, respectively. For the parameter range $p \in (p_1, p_2)$ the attractors A and B coexist and the system demonstrates bistability, see also Fig. 1a. Figure 1c illustrates just one of a number of possible bifurcation scenarios for the appearance of bistability of, for example, steady states (Hale and Kocak 1991; Strogatz 1994; Kuznetsov

1998; Thompson and Stewart 2002): When parameter p increases a stable state B and unstable state C emerge via a saddle-node bifurcation at $p = p_1$ in addition to the existing stable state A. The latter can then collide with C and annihilate in, again, a saddle-node bifurcation at $p = p_2$. Another possible scenario emerges when A is a steady state, and B and C are limit cycles. In this case the bifurcations at $p = p_1$ and $p = p_2$ are a saddle-node bifurcation for limit cycles and a subcritical Andronov-Hopf bifurcation, respectively. In this case the steady state A continues to exist for $p > p_2$, but gets unstable. The latter scenario can be realized, for instance, in the famous Hodgkin-Huxley (HH) model of action potentials in squid giant axons (Hodgkin and Huxley 1952; Rinzel and Miller 1980; Guckenheimer and Labouriau 1993), where the spiking behavior (supported by a stable limit cycle) coexists with a silent regime (supported by a stable steady state).

One of the indications of bistability is the observation of hysteresis (Hale and Kocak 1991; Strogatz 1994; Kuznetsov 1998; Thompson and Stewart 2002), where the system exhibits a delayed response to low, for example, cyclic changes of parameters and, hence, demonstrates a dependence on its history. In the framework of the bifurcation diagram shown in Fig. 1c, the system remains at the stable state A if the parameter slowly increases up to $p = p_2$. Then the system jumps to the state B since A either loses its stability or disappears. If parameter p then slowly decreases, the system will follow the evolution of attractor B even if p becomes smaller than p_2 . The return to attractor A takes place only for $p < p_1$. The following increase of the parameter will repeat the hysteresis loop, see Fig. 1c (red curves).

Multistability occurs at different levels of neuronal systems and constitutes a powerful repertoire of adaptive neuronal dynamical regimes.

Multistability in Single Neurons

Multistability has been observed and investigated for single neurons, both in experimental and modeling studies. Two coexisting stable steady states for the membrane potential have been

found in the squid giant axon under tetraethylammonium chloride (Tasaki and Hagiwara 1957). In the potassium-rich environment short depolarizing pulses can induce an abrupt transition from a lower state of the transmembrane potential to an upper state, and hypopolarizing pulses can reverse the transition (Tasaki 1959). The bistability of tonic spiking and silence has been demonstrated in the squid giant axon under low Ca^{2+} bath concentration, where a single current pulse can induce a transition between these two states (Guttman et al. 1980). More precisely, the repetitive firing can be annihilated by a brief depolarizing or hyperpolarizing pulse, whereas non-annihilating perturbations induce a phase reset. Moreover, the nerve was shown to exhibit a hysteresis when the current is slowly varied through the bistability range. The studies mentioned above provide experimental evidence of bistability of different regimes of the membrane potential in the squid giant axon and a possibility to switch between them under external perturbations, when the system is shifted into the corresponding basin of attraction, see also a theoretical study by Best (1979). The related HH model demonstrates a complicated bifurcation diagram including the coexistence of stable steady states and limit cycles supporting silent and spiking regimes, respectively (Hodgkin and Huxley 1952; Rinzel and Miller 1980; Guckenheimer and Labouriau 1993).

The neurons in the subthalamic nucleus (STN) in rat have been found to exhibit rich patterns of activity including a resting hyperpolarization (down state), a quiescent depolarization (up state), a rhythmic bursting, and a tonic firing (Kass and Mintz 2006). In such a way the STN neurons are quadristable, which also suggests different algorithms for integration and processing of incoming synaptic inputs. A bistable behavior was reported for α -motoneurons in cat, where a brief intracellular depolarizing current pulse can induce a sustained firing which can be terminated by a hyperpolarizing current pulse (Hounsgaard et al. 1984). Such “on”- and “off”-stimuli can switch the neurons between the two coexisting stable states. Moreover, for a slowly increasing and then decreasing depolarizing current a well-

pronounced hysteresis was observed for the firing frequency of the neuron. The stimulation current may thus play a role of a bifurcation parameter leading to different oscillatory regimes, see Fig. 1c. Bistability and hysteresis disappear even under sub-anesthetic doses of barbiturate or ketamin. However, the bistable behavior of the motoneurons can be observed in anesthetized cats during penicillin-induced seizures (Schwindt and Crill 1980).

Emergence and properties of multistability of neural dynamics have extensively been studied by modeling, where the advantages of bifurcation theory (Hale and Kocak 1991; Strogatz 1994; Kuznetsov 1998; Thompson and Stewart 2002) can be used to a great extent. The bifurcation analysis of a 19-compartment hippocampal pyramidal cell model under high-potassium conditions, a related two-compartment reduced model, and the HH equations reveals a parameter region of bistability characterized by repetitive firing and a quiescent state (Hahn and Durand 2001). For the HH model the bistability region is bounded by a fold-cycle bifurcation (saddle-node bifurcation for limit cycles), after which limit cycles disappear, from one side, and a subcritical Andronov-Hopf bifurcation, where the fixed point gets unstable, from another side, see also Guckenheimer and Labouriau (1993) for a review of bifurcations in the HH model. For the two-compartment reduced model, the regimes of stable spiking, low-amplitude oscillations, rest state, and repetitive bursting have been found with the bistability of the latter two, which is mediated by a subcritical Andronov-Hopf and a torus bifurcation (Hahn and Durand 2001). The bistability of a rest state and a firing mode in cerebellar Purkinje cells has been shown to be mediated by a saddle-node bifurcation of steady states in the transition from rest to firing and a saddle homoclinic bifurcation from firing to rest (Fernandez et al. 2007). The behavior of the cell and its model can be switched from rest to firing and from firing to rest by a brief and strong enough input (Loewenstein et al. 2005; Fernandez et al. 2007). The bistability of tonic firing and bursting was also found and studied in a detailed two-compartment conductance-based cortical neuron model for elevated extracellular

potassium concentration (Fröhlich and Bazhenov 2006).

A generic biophysical mechanism underlying the emergence of different dynamical regimes in a leech heart interneuron and its model has been studied by Cymbalyuk et al. (2002). A bistability of bursting and silence, bursting and tonic spiking, and tonic spiking and silence has been illustrated in a two-parameter bifurcation diagram. The coexistence of stable tonic spiking and bursting behaviors can be explained by the Lukyanov-Shilnikov bifurcation of a saddlenode periodic orbit with noncentral homoclinics (Shilnikov et al. 2005). A detailed bifurcation analysis of the bistability of the bursting and silence regimes of a model of a leech heart interneuron revealed that the bistability range in leak current parameter space is bounded by a subcritical Andronov-Hopf bifurcation of a steady state and a homoclinic bifurcation for a saddle periodic orbit of unstable hyperpolarized subthreshold oscillations (Malashchenko et al. 2011). The stable manifold of the latter separates the basins of attraction of the stable bursting and silence regimes. Six types of multistability have been reported for a low-dimensional neural model of a single leech heart interneuron based on slow calcium current (Malashchenko et al. 2011). There may coexist spiking and silence, spiking and subthreshold oscillations, spiking and bursting, bursting and subthreshold oscillations, bursting and silence as well as bursting, subthreshold oscillations, and silence.

As follows from the above brief overview, multistability is a generic phenomenon already at the level of single neurons. This is also supported by study of Marin et al. (2013), where a large database of isolated leech heart interneuron models was examined with respect to coexisting stable states. It appears that in 91% of 2223 cases of unique endogenous bursters, the multistability of bursting and silent regimes is present in some range of the leak conductance parameter. Such a prevalence of multistability in models of single neurons has to be taken into account at the investigation of neural networks, where the multistability can further be enhanced or even created by interactions.

Multistability in Neural Networks

When a population of bistable units gets weakly coupled in a network, the intrinsic bistability of individual nodes is translated into a pronounced multistability of stable states of the network as proved by Mackay and Sepulchre (1995) for a large class of interaction types. However, even for a monostable dynamics of individual elements, the interactions can induce additional attractors coexisting in the state space of coupled neurons. A single HH model neuron in a monostable regime can nevertheless demonstrate a great multistability if a self-interaction is introduced via a recurrent delayed loop (Foss et al. 1996). This has also been observed experimentally for a periodically spiking aplysia motoneuron reciprocally connected to a computer (Foss and Milton 2000).

Two (or more) phase oscillators, each exhibiting simple periodic oscillations, can synchronize at different phase differences and synchronization frequencies depending on initial conditions if coupled with delay (Schuster and Wagner 1989; Lysyansky et al. 2008; D’Huys et al. 2008; Popovych et al. 2010). Two neurons with self- and mutual-inhibition and receiving a common excitatory input demonstrate several distinct firing patterns which change in discrete steps as the stimulus frequency varies (Harmon 1964). The considered network motif of reciprocally inhibiting pairs of neurons can control the antagonistic muscular systems, is able to store several patterns of motion, and exhibits a hysteresis at the transition between them. Coexisting polyrhythmic synchronization of three monobursting neurons has been found in simple network motifs of reciprocally inhibitory connections (Shilnikov et al. 2008), which can serve as building blocks for larger inhibitory-excitatory networks of, for example, central pattern generators (Briggman and Kristan 2008).

For a more complex coupling topology, the presence of at least one positive loop is a necessary (but not sufficient) condition for the emergence of multiple states (Thomas 1981; Cinquin and Demongeot 2002), which is of particular importance for the analysis of biological systems (Ferrell and Machleder 1998; Laurent and

Kellersohn 1999). This property can be illustrated on a simple network of oscillatory neurons coupled in a feed-forward loop (Fig. 2a) which seems to be a generic coupling topology in the nervous system (Alexander et al. 1986; Ahissar and Kleinfeld 2003) and has been investigated in the context of pathological neural dynamics (Volkman et al. 1996; Bergman and Deuschl 2002; Fogelson et al. 2006; Hammond et al. 2008), excitable cardiac tissue (Courtemanche et al. 1993), orientation tuning in visual cortex (Ben-Yishai et al. 1997), and central pattern generators (Golubitsky et al. 1999). For such systems a multitude of stable states may coexist which include in-phase synchronized states, where the neurons fire nearly simultaneously (Fig. 2b), as well as traveling waves with one or more firing fronts propagating either in the direction of coupling (Fig. 2c) or in opposite direction (Fig. 2d) (see Refs. Ermentrout 1985; Dodla et al. 2004; Perlikowski et al. 2010; Popovych et al. 2011). In spite of the monostable dynamics of the individual

neurons which can fire only at a single frequency, the ring-coupled neurons (Fig. 2a) synchronize and, depending on initial conditions, can spike with different phase shifts between neighboring neurons and also at very different synchronization frequencies selected from a certain interval (Fig. 2e). Including a communication delay in the coupling significantly enhances the multistability, where several firing patterns of the same spatial configuration (the same number of firing fronts), but with different oscillation frequency can coexist (Fig. 2e).

The intrinsic multistability of coupled neurons enables to select particular firing patterns of the network out of a repertoire of existing stable patterns. This can for instance be done by a brief transient perturbation shifting the system from one basin of attraction to another (Fig. 1a). The parameters of the stimulation signal, such as intensity, duration, and timing, have to be appropriately calibrated, which can be achieved with the use of the phase response curves (PRC)

Coexistence of Pathological and Functional Neuronal Regimes, Fig. 2 (a) Ring of unidirectionally coupled neurons. (b–d) Periodic spatiotemporal patterns appearing for identical synaptic weights and communication delays: (b) in-phase synchronization, (c) and (d) traveling waves with one firing front propagating along ($k=1$) and against ($k=-1$) the direction of coupling, respectively, see (a). The membrane potential V_j is encoded in color versus time

and oscillator number. (e) Co-existence of multiple stable traveling waves, where the spiking frequency of synchronized neurons is depicted versus the number of firing fronts k for different values of the delay τ in the coupling as indicated in the plot. (First published in Popovych et al. (2011). Copyright (2011) by the American Physical Society)

(Schultheiss et al. 2011), as suggested by Canavier et al. (1999). Other approaches include a stabilization of a targeted traveling wave by a delayed feedback stimulation (Montgomery and Silber 2004) or designing and stabilization of a desired firing pattern by an adjustment of communication delays or/and synaptic weights (Popovych et al. 2011; Yanchuk et al. 2011).

Feedback mechanisms are essentially involved in the function of a biological switch which can guide the transition of a biological system to particular functional regimes, for example, for the expression of one or another gene and protein production, or even make an irreversible turn into one of several possible distinct evolution pathways as, for example, for cell differentiation (Ferrell and Machleder 1998; Laurent and Kellersohn 1999; Cinquin and Demongeot 2002). A biological switch is a bistable (multistable) system which can remember a stimulus long after the stimulus has been removed and behaves like a light switch – once it is flipped, it will stay on (Ferrell 1998), see hysteresis in Fig. 1c. A simple biological switch has been discussed by Cherry and Adler (2000), where two coupled subsystems negatively regulate each other. Such a switch has two stable states, one in which the first element is in “on-state” and the second is in “off-state,” and another in which these states are reversed. A transient input signal can force the system into a particular steady state which persists after the input is removed. In such a way the system “remembers” what kind of input signal it was last exposed to, although it is composed from elements that themselves have no memory. Such a switch may be a simple component of a more complex regulatory network. The multistability of a system with feedback can be deduced from the behavior of the open-loop system when the feedback is blocked by a simple graphical method as suggested by Angeli et al. (2004).

The neurons in the brain are highly interconnected through a complicated coupling topology on both intra- and inter-population levels (Sporns 2011). Such a complexity has also been reflected in a variety of neural model networks of different architectures and levels of

detailing (Arbib 2003). Hence, one can anticipate a great multistability of many dynamical regimes in such networks. For example, an experimental study by Sasaki et al. (2007) investigated the spontaneous CA3 network activity in hippocampal slice cultures with functional multineuron calcium imaging. Several network states were revealed, where the system stabilizes and stays for tens of seconds in a certain configuration with sudden jumps to the next state. Such a behavior can suggest that the network dynamics is governed by local attractor-like dynamics with transitions from one attractor to the next. Repeated patterns of spontaneous neural activity have been found in cortical slice cultures, which can be maintained by the underlying neural network for many hours of observation (Beggs and Plenz 2004).

Functional Regimes

The multistability of neural populations may comprise healthy as well as pathological dynamical regimes. Examples of multistable functional regimes include multistable perception, varieties of motor patterns in the context of motor control, spontaneous neuronal activity of the brain at rest, etc. (Schöner et al. 1990; van Emmerik and Wagenaar 1996; Leopold and Logothetis 1999; Moreno-Bote et al. 2007; Briggman and Kristan 2008; Haken 2008; Sterzer et al. 2009; Deco et al. 2009; Lewis et al. 2009; Braun and Mattia 2010; Freyer et al. 2011).

Multistable perception can be explored when, for example, an ambiguous sensory stimulus (e.g., ambiguous picture such as the Necker cube, face-vase or young-old woman illusions) is presented, or when the eyes view two incongruent images in the framework of binocular rivalry (Ditzinger and Haken 1989; Leopold and Logothetis 1999; Sterzer et al. 2009; Braun and Mattia 2010). The perception will switch back and forth from one to another appearance and interpretation of the stimulus, which continues as long as the pictures are perceived, and the transitions with episodes of mixed or intermediate appearance also include self-transitions (Brascamp et al. 2006). Multistable perception is not restricted to the visual system. In fact, striking similarities in the

multistable behavior have also been observed for auditory and tactile sensory domains (Pressnitzer and Hupe 2006; Carter et al. 2008).

In multistable visual perception, the neurons in the visual system get strongly modulated during perceptual alternations such that a kind of competition between central stimulus representations can be hypothesized (Leopold and Logothetis 1999), see also Ditzinger and Haken (1989). Neuronal activity of different brain areas supports the sustained perceptual dominance of a certain pattern or participates in perceptual changes (Tong et al. 1998; Lumer et al. 1998; Sterzer et al. 2009). In this way, the brain seems to form different states of activity corresponding to the perception of different stimuli and switch between them when viewing ambiguous or dissimilar images. Macroscopic models for such processes were developed by Ditzinger and Haken (1989). It was found that such switches in the perception have a stochastic character and contrasted to the reciprocal-inhibition models of bistable perception in which fatigue initiates perceptual reversals (Taylor and Aldridge 1974; Leopold and Logothetis 1999). The statistical distribution of time intervals spent on each percept is unimodal and asymmetric and can be fitted by the gamma distribution, and subsequent intervals appear to be largely independent of each other (Fox and Herrmann 1967; Borsellino et al. 1972).

The dynamics observed in the context of perceptual multistability can be compared with that of the decision-making processes, where the framework of coexisting different attracting states is used (Deco et al. 2009; Braun and Mattia 2010). It can be explained by models having several stable states (attractors) representing different percepts (Fig. 1a), and the system visits one or another attractor under the action of random perturbations (Brascamp et al. 2006). Such an approach has successfully been applied to detailed mean-field and network models of spiking neurons extended by a weak adaptation process (Moreno-Bote et al. 2007), see also Gigante et al. (2009) for a more complex representation of attracting states for multistable perception. The attractor mechanism is also supported by results of Kim et al. (2006) showing that binocular rivalry

can exhibit the phenomenon of stochastic resonance (Moss et al. 2004). Random perturbations of the neural dynamics can, for instance, originate from a sporadic signal loss at the level of signal processing in the brain, eye saccades and blinking, finite-size induced fluctuations in neural networks, spiking variability, internal or external noise, etc. Randomness can even have a functional role, when the brain intentionally introduces perturbations of the vision in order to reorganize the sensory input and its processing and archive a more stable exploration and representation of the surrounding world (Carpenter 1999; Leopold and Logothetis 1999; Brascamp et al. 2006).

Multistability is a common phenomenon in the motor system which can generate a variety of recognizably different patterns of behavior (Schöner and Kelso 1988; Marder and Calabrese 1996; Briggman and Kristan 2008). Distributed control and modular organization of the motor circuits greatly contribute to multistable dynamics. The building blocks properties of the pattern generating circuits can be collected into a certain “alphabet” on the cellular, synaptic, and network levels, which essentially contribute to the functions and to the multitude of possible regimes produced by such systems (Getting 1989). These properties and, as a result, the dynamics of the neural circuits can be modified to a great extent by synaptic inputs or neuromodulators (Marder and Calabrese 1996; Briggman and Kristan 2008). The organizational principles of neural networks indicate that a single anatomical set of neurons may perform multiple tasks, which leads to the notion of multifunctional pattern-generating circuits (Getting 1989; Briggman and Kristan 2008).

A detailed examination of the flight behavior of the blowfly revealed a few discrete and distinct patterns of the neuronal spike trains controlling the corresponding muscle activity (Wyman 1966). During the flight, several different motor units of a single muscle receive repeated sequences of spikes from motoneurons, where the phase relations between spikes across different spike trains are stably preserved independently of the oscillation frequency. Occasionally, a transition to a different firing pattern can happen such that any

inter-unit sequential ordering of the spikes is possible. The group of motoneurons controlling the flight thus demonstrates a kind of “phase multistability” of a few stable output patterns corresponding to different possible combinations of preferred phase positions of the spikes (Wyman 1966). Another example of multistability in the motor system is provided by the central pattern generator (CPG) of the lobster involved in the generation of the “pyloric” motor rhythm (Russell and Hartline 1982). The motoneurons of the lobster CPG can be switched from the rest state to the bursting and back by brief depolarizing and hypopolarizing current pulses, respectively, in an all-or-none fashion. This fundamental feature of bistability of the motoneurons may play a role in the formation of the pyloric motor rhythm when neurons interact with the synaptic network of the CPG.

In experiments on voluntary cyclic movements of two hands or fingers, an abrupt transition from asymmetrical, anti-phase mode to symmetrical, in-phase mode of oscillations has been reported when the oscillation frequency was continuously increased (Kelso 1984; Kelso and Scholz 1985). While only one (symmetrical, in-phase) mode can be observed beyond the transition, both modes coexist for slow oscillations, and the system stays in the symmetrical mode and does not return to its initially prepared (asymmetrical, anti-phase) state when the cycling frequency is reduced. The observed hysteresis phenomenon, see Fig. 1c, and bistability were investigated in modeling studies (Haken et al. 1985; Schöner et al. 1986). Under the influence of random forces, the phase transition is characterized by two important properties referred to as *critical fluctuations* (Haken 1983), where the variables exhibit enhanced fluctuations close to the transition, and *critical slowing down* (Haken 1983), where the system demonstrates an increased relaxation time to the mode that turns unstable at the transition (Kelso and Scholz 1985; Schöner et al. 1986). These properties can serve as an indication of the bifurcation and can be assessed in experimental setups, where the noise is inevitable. Overall, these findings indicate the important role of the self-organization processes in motor control (Kelso 1997; Haken 2008).

In a neuronal model of the spinal pattern generator for the swimming in the lamprey, a multistability of a silent regime (steady state) and oscillatory behavior (limit cycle) can be mediated by saddle-node bifurcations of the fixed points and limit cycles (Jung et al. 1996). The most effective network models of CPG for walking can be decomposed into dynamical modules which demonstrate a well-pronounced multistability and enable a switching between multiple stable output configurations (Chiel et al. 1999; Beer et al. 1999). To describe the gaits of the quadrupedal locomotion for, for example, horses, a set of collective variables of the relative phases can be introduced, where the stable gait patterns are represented as attractors (Schöner et al. 1990). In this framework, continuous and abrupt gait transitions can be investigated, where the latter can be accompanied by stability loss of the corresponding attractors and the presence of hysteresis. Similar transitions, multistability, and hysteresis can also occur in human bipedal walking (van Emmerik and Wagenaar 1996).

Spontaneous activity of the brain at rest, which can be defined as the firing of neurons measured in the absence of (sensory) stimuli or task activations (Ringach 2009; Deco and Corbetta 2011), is a further example for the emerging of multistability of functional regimes. There is converging evidence for spontaneous activity being highly structured in both space and time, which suggests the existence of underlying attractor states (Plenz and Thiagarajan 2007; Ringach 2009; Deco and Corbetta 2011). The ongoing neural activity of resting brain states also demonstrates the presence of several attracting states and a spontaneous and irregular switching between them. For example, the instantaneous power of the human electroencephalographic (EEG) data exhibits erratic switching in the alpha band (~10 Hz) between low- and high-power modes as time evolves (Freyer et al. 2011). A sophisticated corticothalamic mean-field model predicts that these fluctuations arise from the noise-induced jumps between two distinct probability distributions with overlapping tails which emerge from a coexisting stable steady state and a limit cycle perturbed by noise. The latter includes additive

as well as state-dependent (multiplicative) components. The bifurcation diagram has the form as in Fig. 1c, where state *A* is a stable equilibrium bifurcating via a subcritical Andronov-Hopf bifurcation, and *B* and *C* are stable and unstable limit cycles, respectively (Freyer et al. 2011).

For spontaneous brain activity at rest, several large-scale resting state networks (RSN) can be identified by functional magnetic resonance imaging (fMRI), which include distinct brain areas being functionally connected by a significant correlation of their fMRI signals (Deco and Corbetta 2011). Since the topography of RSNs closely resembles the structure of jointly task-activated brain networks, different RSNs can be viewed as sets of attractor states shaped during repetitive activation by the task performance and maintained by intrinsic dynamics at rest (Lewis et al. 2009; Deco and Corbetta 2011). The measured spontaneous fluctuations of the macroscopic resting activity can be modeled by the dynamics of an ensemble of Wilson-Cowan mean-field models (Wilson and Cowan 1972) weakly coupled with time delay (Deco et al. 2009). Noise can induce a switching between multistable states of enhanced synchronization of either of the subnetworks with characteristic effect of stochastic resonance (Moss et al. 2004). These active fluctuations of the spontaneous activity between multistable states can set up the brain for external signals that can trigger the activation of one of the available multistable states (Deco et al. 2009; Deco and Corbetta 2011): “Metaphorically speaking, the resting state is like a tennis player waiting for the service of his opponent. The player is not static, but continues to move with small lateral jumps left and right to be able to react more promptly to a fast ball.”

Pathological Regimes

Several neurological disorders attracted large attention of the modeling studies, which can contribute to a better understanding of the mechanisms of pathological neuronal dynamics. In many cases such a dynamics involves the coexistence of two or more attracting states, where the brain switches between them in generating abnormal activity. Epilepsy is one of these diseases. The nonstationarity in time series from intracranial

depth and subdural EEG recordings of patients with temporal lobe epilepsy can be explained by transitions between two states of the mesoscopic collection of neurons contributing to the measured signals, and the transition probability increases as a seizure is approached (Manuca et al. 1998). Neuronal networks involved in epilepsy can be considered to possess a multistable dynamics consisting of, at least, two states: An interictal one characterized by normal ongoing activity, and another one that is characterized by the paroxysmal occurrence of synchronous oscillations (seizure) (da Silva et al. 2003a, b). The transitions between these two attractors can be caused by different endogenous or exogenous factors resulting in random fluctuations of some variables or variation of critical parameters. Such fluctuations lead to either sudden jumps between attractors or their gradual interchanging deformations (da Silva et al. 2003a, b; Breakspear et al. 2006). Several studies were devoted to an irregular dynamics of the “seizure” attractors characterized by positive Lyapunov exponents, which indicates the presence of chaotic regimes, and the dimension of such attractors may be significantly reduced as compared to “normal” ones (Babloyantz and Destexhe 1986; Kowalik et al. 2001).

Multistability comprising physiological sparse and pathological tonic-clonic activity was demonstrated in a realistic model network of two-compartment conductance-based neurons including extracellular potassium concentration dynamics (Fröhlich et al. 2010). For the same parameters and identical afferent input level, transient perturbations can switch the cortical network between these two states inducing, in this way, a long-lasting change in brain dynamics and replacing the functional regime by a pathological one. In the above framework of a “multistability-mediated dynamic repertoire,” the ictal state is characterized by a different behavior and its underlying mechanism as compared to the inter-ictal states. For example, the synaptic efficiency can be depressed during seizure contrary to its behavior in the non-seizure states, which can contribute to the mechanism of seizure termination (Vincent et al. 2011).

Also for Parkinson's disease (PD) there is an evidence of multistable dynamics. For instance, the recording of local field potentials (LFP) from the STN of patients with PD clearly demonstrates the emergence of a 300-Hz rhythm after levodopa administration, which is dopamine- and movement-dependent (Foffani et al. 2003). No such consistent rhythm has been found in the pathological regime in the absence of dopaminergic medication at rest, which could contribute to movement abnormalities in PD and reflect a bistable compound of nuclear activity at its transition to physiological functioning. Moreover, also in the two other major frequency bands, theta band (< 8 Hz) and beta band (8–30 Hz) (Brown and Williams 2005) pathological neuronal synchrony may occur. While beta band activity is related to akinesia and rigidity (Kühn et al. 2006), theta band oscillations are connected to tremor (Wang et al. 2005; Reck et al. 2009; Tass et al. 2010). Abnormal synchronization processes in these frequency bands served as targets for the development of stimulation techniques for desynchronization (Tass 1999, 2003b), ultimately aiming at an unlearning of abnormal synchrony by shifting the affected neural systems to more favorable attractors (Tass and Majtanik 2006), see below.

Furthermore, a repertoire of activity patterns of STN neurons (Kass and Mintz 2006) can support the emergence of multistable dynamics at the network level. The neurons in the pedunculopontine nucleus (PPN), which has been suggested as a target for deep brain stimulation (DBS) to improve gait and postural instability (Plaha and Gill 2005), exhibit a bistable behavior of fast and slow spiking (Lourens et al. 2011). DBS of PPN neurons in the pathological case can assist them to return to their natural oscillations, which in turn facilitates locomotion and postural control. The effect of STN DBS on rigidity, one of the cardinal symptoms of PD, can also be accounted for by multistability of motoneuron firing, see Hounsgaard et al. (1984). The stimulation can reduce the neuromodulatory input to the motoneurons which in turn switch from the state of persistent inward current characterized by self-sustained firing to the state, where the inward current is decreased or even suppressed, and the

rigidity is suppressed as well (Raoul et al. 2012). The pathogenesis of PD has been modeled at the molecular level, where a feedback-induced biochemical bistability was suggested to play a central role at the transition from a “healthy” homeostatic state to alternative “disease” state with stable high concentrations of molecules associated with PD (Cloutier et al. 2012). The presented simple bistable bifurcation diagram as in Fig. 1c allows a plausible interpretation of the impact of a variety of risk factors on susceptibility, severity, and multi-timescale progression of the disease.

The motoneurons' multistability (Hounsgaard et al. 1984) is involved in long-lasting epochs of muscle cramps which can regularly be evoked in patients by a short-lasting excitatory input to motoneurons and continues for more than 1 min (Baldissera et al. 1991). It has been suggested that such a perturbation shifts the motoneurons to a self-sustained depolarization and repetitive firing, which provokes the cramps. A suprathreshold stimulation was shown to terminate this activity by repolarizing the motoneurons and shift the motoneurons back to their low-level state. This result suggests that the mechanism which generates the cramps is intrinsic to the motoneurons' somata and based on the bistability of motoneuronal membrane (Baldissera et al. 1991) observed in other experiments (Hounsgaard et al. 1984). The susceptibility of the motoneurons to such a bistability can be enhanced by factors that modify the potassium equilibrium potential or conductance. The post-stimulation electromyographic (EMG) afterdischarges, which were observed in patients with peripheral neuropathies and with muscle cramps as compared to patients without cramps (Parisi et al. 2000), further support the importance of the above bistable dynamics of motoneurons in the generation of cramps. The afterdischarges are considered to be the result of a hyperactive bistable state of motoneurons which may occur spontaneously or may be triggered by a brief muscle contraction as well as by a repetitive stimulation of the peripheral nerve (Parisi et al. 2000).

The modeling of afterdischarges (continued spiking after a brief stimulus) in the framework

of paroxysmal symptoms, such as paroxysmal attacks of pain or muscle spasm, can reveal possible mechanisms of the underlying bistability that was found to be caused by slow positive feedback (Coggan et al. 2011). Perturbations can shift the system from the basin of attraction of a steady state (silent regime) to the basin of attraction of coexisting stable limit cycle (spiking regime), in this way initiating afterdischarges. In this state, an even slower negative feedback, such as intracellular sodium accumulation, is activated and destroys the attractor, which terminates the afterdischarges (Coggan et al. 2011).

Another example of multistable behavior related to pathological regimes can be the case of bipolar disorders which are characterized by recurrent and alternating episodes of mania and depression (Goldbeter 2011). A spontaneous and recurrent switching between mutually exclusive states of the disorder can be observed and explained by a model of two neural circuits that inhibit each other. Multistability has also been discussed in the context of human cancer by identifying bistable biological switches which could lock the networks of protein-protein interactions and gene regulations in a disease state, where some sets of genes could be abnormally overexpressed or repressed (Shiraishi et al. 2010).

Time-Varying Parameters

Multistability is defined as coexistence of several stable states (attractors) for fixed parameter values (Fig. 1a), and perturbation of system variables can elicit sudden changes of the system's behavior by switching between different attractors. If parameters vary, the system can undergo transitions between qualitatively different dynamics, when a single attractor bifurcates, but this can, however, happen also in a monostable case. On the other hand, the parameters of complex biological systems are not fully frozen, but rather undergo a certain degree of variation while adapting to changes in the environment, input, underlying activity, etc. In the multistable situation a cyclic parameter variation may lead to the manifestation of hysteresis and sequential emergence of

different regimes corresponding to different attractors (Fig. 1c). This mechanism is the basis of burst generation involving a cyclic transition between two attractors: a stable steady state (hyperpolarized state) and a limit cycle (spiking) (Izhikevich 2000). In this case a slowly varying parameter depends on system's dynamics and is considered as one more dynamical variable.

Dynamics acting on different time scales are, in fact, of fundamental importance to biology (Haken 1992; Izhikevich 2000). For instance, in the context of the multistable perception, a specific set of so-called attention parameters was introduced (Ditzinger and Haken 1989). The latter become time dependent because of a saturation of synaptic connections (Ditzinger and Haken 1989). In this framework oscillations of the perception naturally arise, which are in excellent agreement with experimental findings (Ditzinger and Haken 1989). For epileptic tonic-clonic brain activity, a cyclic variation of a certain parameter may induce transitions between pathological and normal states in a hysteresis-like manner (Breakspear et al. 2006), and the state-dependent depression of synaptic efficiency may serve as a mechanism of seizure termination (Vincent et al. 2011).

It is well-known that synapses are involved in adaptation processes, where their efficacy is governed by spike timing-dependent plasticity (STDP) (Gerstner et al. 1996; Markram et al. 1997; Feldman 2000; Wittenberg and Wang 2006; Caporale and Dan 2008). An example of the STDP function is illustrated in Fig. 3a (see also Refs. Bi and Poo 1998; Bi 2002). The synaptic weights are updated in a point-like process by the increment $W(\Delta t)$ after pre- or post-synaptic neurons fired. For such a plasticity rule the synaptic weight is potentiated or depressed depending on whether the post-synaptic firing follows or advances the pre-synaptic firing, respectively. STDP can lead to multistability where states with different connectivity and different collective dynamics may coexist. If, for instance, the initial coupling is weak, the neurons get desynchronized, and the spiking time differences Δt get broadly (e.g., uniformly) distributed. Then STDP (Fig. 3a) leads to a further

Coexistence of Pathological and Functional Neuronal Regimes, Fig. 3 (a) Normalized plasticity function versus the difference of the spike/burst timing of post- and pre-synaptic neuron $\Delta t = t_{\text{post}} - t_{\text{pre}}$. (b) The average update rate of synaptic weights $\Delta k(\epsilon) = \int W(\xi)\rho(\xi)d\xi$ for the uniform distribution density $\rho = 1/2\epsilon$ of $\Delta t \in [-\epsilon, \epsilon]$

suppression of the coupling, see Fig. 3b for large ϵ where $\Delta k < 0$, the neurons remain desynchronized, and a weakly coupled desynchronized state gets stabilized (Fig. 4). On the other hand, if the initial coupling is strong, the neurons fire synchronously, that is, their spiking time differences are narrowly distributed around zero, see Fig. 3b for small ϵ where $\Delta k > 0$, and the synaptic weights get further potentiated. Such initial conditions result in a strongly coupled synchronized state (Fig. 4). Along with the two regimes, some other states with intermediate coupling strength and synchronization may coexist as well (Fig. 4).

Neuronal synchronization is essentially involved in normal brain function, ranging from sensory information processing to cognitive and motor function (Singer 1993; Engel et al. 2001). Abnormal neural synchrony, on the other hand, can significantly impair neural processes and is a hallmark of several neurological disorders like Parkinson's disease or tinnitus (Hammond et al. 2007; Roberts et al. 2010). Hence, it was suggested to specifically counteract abnormal neural synchrony by desynchronization achieved with computationally designed stimulation techniques (Tass 1999). Accordingly, methods for

synchronization control developed with methods of dynamical systems (Tass 1999, 2001, 2003b; Rosenblum and Pikovsky 2004; Popovych et al. 2005; Popovych and Tass 2010) may turn out to have significant clinical applications. Desynchronizing stimulation can induce a rewiring of the synaptic connections in which the synaptic weights get depressed (Tass and Majtanik 2006). After sufficiently long stimulation, the amount of coupling in the network is significantly reduced, and the neural population is shifted to a healthy model attractor with a weakly coupled and desynchronized regime (anti-kindling) (Tass and Majtanik 2006).

The anti-kindling process in a neural network with STDP is illustrated in Fig. 5 for coordinated reset (CR) stimulation suggested for desynchronizing electrical DBS (Tass 2003a, b; Tass and Majtanik 2006) and for the treatment of tinnitus by noninvasive acoustic stimulation (Tass and Popovych 2012). For both stimulation modalities, that is, for somatic electrical and synaptically mediated (e.g., sensory) stimulation, there exists a range of stimulation intensities, where CR stimulation can effectively shift the collective dynamics of the stimulated neural network to a weakly coupled and desynchronized regime which stably persists after cessation of stimulation (Fig. 5, green curves) (Popovych and Tass 2012). This corresponds to long-lasting therapeutic effects of CR stimulation, which has been confirmed by several pre-clinical and clinical studies. CR-induced long-lasting desynchronization has experimentally been verified in rat hippocampal slice rendered epileptic by magnesium withdrawal (Tass et al. 2009). In addition, electrical CR stimulation of the STN was tested in a non-human primate model of parkinsonism of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated macaque monkeys, where sustained therapeutic long-lasting aftereffects on motor function in MPTP monkeys were observed after low-dosage CR stimulation (Tass et al. 2012a). Lasting aftereffects of electrical CR stimulation of the STN were observed in Parkinson patients (Adamchic et al. 2014). Moreover, noninvasive sensory (acoustic) CR stimulation has already been

Coexistence of Pathological and Functional Neuronal Regimes, Fig. 4 Plasticity-induced multistability of synchronized and desynchronized states in a neural network with STDP. **(a)** Time courses of the mean (averaged across the network) synaptic weights $C(t)$ for different initial coupling matrices $\{c_{ij}(0)\}$ whose elements are Gaussian distributed around the mean value c_0 indicated in the legend. **(b)** Time courses of the LFP of four different stable regimes observed for the initial coupling matrices with mean value c_0 indicated in the legend. LFP

oscillations of different amplitude reflect the extent of synchronization among neurons. **(c)** The corresponding coupling matrices developed in the neural ensemble due to STDP for four different stable states. The initial mean values c_0 are indicated in the plots. The closely (distantly) located neurons interact via excitatory (inhibitory) connections according to the Mexican hat spatial profile with periodic boundary conditions, see Popovych and Tass (2012) for details

applied for the treatment of chronic subjective tinnitus and is turned out to significantly counteract both tinnitus symptoms and the underlying pathological neuronal synchronization (Tass et al. 2012b) by normalizing the effective brain connectivity and restoring the functional patterns of activity (Silchenko et al. 2013; Adamchic et al. 2013).

Summary

The theoretical framework of attractors and multistability established for nonlinear dynamical systems can effectively be applied to the analysis of realistic biological systems, in particular, to the investigation of neuronal dynamics. Multistability enables to switch system from one state to another

Coexistence of Pathological and Functional Neuronal Regimes, Fig. 5 Stimulation-induced rewiring and desynchronization of the neural ensemble with STDP by desynchronizing coordinated (CR) stimulation. The time courses of the mean synaptic weights $C(t)$ are plotted for weak, optimal, and strong stimulation intensities as indicated in the legends. The stimulation time interval is

indicated by a red bar and by vertical dashed lines for direct electrical CR stimulation, indirect excitatory CR stimulation, and indirect inhibitory CR stimulation (as indicated in the plots) administered to a strongly coupled and synchronized regime as in Fig. 4 for $c_0 = 0.5$, see Popovych and Tass (2012) for details

appropriate perturbation. The emergence of hysteresis, which can be induced by a cyclic parameter variation, provides further evidence for co-existing attractors. To understand the mechanisms underlying the neuronal dynamics, it is important to figure out whether the observed behavior belongs to a “parameter-mediated dynamic repertoire” or to a “multistability-mediated dynamic repertoire” (Fröhlich et al. 2010). In the latter case, a brief appropriate stimulus may suffice to switch the system to another, possibly more preferable state as explained above, whereas to control parameters is a much more difficult task, in particular, in neuronal networks of the brain. The modeling approaches at different levels of complexity significantly help in solving the above problem, where the study of bifurcation mechanisms as well as other properties of attractors and the structure of the state space can

substantially contribute as illustrated above. In this way, the model-based development of control methods with the use of methods from nonlinear dynamics and especially the phenomenon of multistability can result in effective techniques for the treatment of a variety of neurological diseases.

Glossary

Attractor An attractor is a closed invariant set in the state space of a system to which many initial conditions (configurations) of the system converge as time evolves. The union of all initial conditions approaching an attractor constitutes its basin of attraction and has a positive measure, that is, it occupies a positive volume of the state space. An attractor cannot be

decomposed into smaller attractors with distinct basins of attraction. In the theory of dynamical systems a number of different types of attractors have been discovered including steady states, limit cycles, and chaotic attractors, where the latter two are characterized by periodic and irregular oscillations, respectively.

Bifurcation A bifurcation denotes a sudden qualitative change of the system's dynamics as one or more parameters vary over a bifurcation point. A number of local and global bifurcations are known including saddle-node (fold), Andronov-Hopf, period-doubling (flip), transcritical, pitchfork, Neimark-Sacker (torus), saddle-node on invariant circle (SNIC), blue sky catastrophe, homoclinic, and hereoclinic bifurcations. Bifurcations can involve steady states (fixed points), periodic orbits (limit cycles), or more complicated objects like chaotic attractors. Bifurcation theory describes the bifurcation conditions and dynamics of the system before and after the bifurcation. The bifurcation transition gets more complicated with increasing codimension of a bifurcation which is the number of varying parameters necessary for the bifurcation to occur.

Multistability Multistability is a property of a system to have two (in the case of bistability) or more different attractors which coexist in the state space for the same values of system parameters. These states can be realized for different initial conditions or under perturbations shifting the system state to the corresponding basins of attraction. In biological systems multistability is a common phenomenon.

Probabilistic models of cognition; Rational models of cognition

Definition

Bayesian models provide a principled way to deal with uncertainty. In cognitive tasks the uncertainty is mainly in how to represent the observed

data, as there is usually not enough data to uniquely determine the representation. Bayesian models of cognition implement a general method for dealing with representational uncertainty which can be applied to explain human performance in various cognitive tasks.

Detailed Description

Cognitive tasks are full of uncertainty. From deciding what to call a new object, to determining what causes what in the environment, to learning a language, there is generally not enough information to uniquely determine the answer. Bayesian models of cognition provide a principled way to deal with this uncertainty, using probability theory to evaluate hypotheses and produce responses. Below, I briefly review three key areas in which Bayesian models of cognition have been applied: categorization, learning and causal inference, and language.

Categorization

Studies of categorization investigate how people group stimuli and generalize from previous experience to new situations. Classically, categories were defined by a set of necessary and sufficient conditions that determined whether an object was a member of the category. However, all-or-none category membership clashes with empirical investigations demonstrating that in human categorization, objects are more or less members of a category (Rosch 1973; Rosch and Mervis 1975).

Bayesian models of cognition provide a link between the classical definition and empirical observations. People might assume that a necessary and sufficient set of conditions describe the category, but do not know the exact set of conditions. For example, it might be unclear exactly what wavelengths of light define the category of red. Uncertainty about the boundary can be dealt with in a Bayesian model, which produces a graded category as a result of combining sets of more or less likely conditions (Shepard 1987; Tenenbaum and Griffiths 2001).

Another classic representational question in categorization is whether categories are represented by prototypes or exemplars. Prototype representations compare new stimuli to a single abstract example, while exemplar representations compare new stimuli to all previously observed examples (Medin and Schaffer 1978; Nosofsky 1986; Reed 1972). Each representation is appropriate for different problems, and Bayesian models have been used to combine these representations together, weighting representations by how well they suit the problem (Anderson 1991).

Learning and Causal Inference

Learning research has a long history in cognition, with initial investigations focusing how animals were able to associate stimuli such as tones and lights with particular rewards. Although early work investigated associations, the demonstrated power and flexibility of animal learning indicated that more complex representations were used (Rescorla 1988).

This type of learning has been modeled in a Bayesian framework as causal inference, in which the animal attempts to determine the causal structure of the environment in order to make predictions (Courville et al. 2006). Learning a causal structure is extremely difficult, and for some learning problems even infinite observations of outcomes are not enough to uniquely determine the structure. Bayesian models deal with this uncertainty and can even take into account vast spaces of possible structural forms (Kemp and Tenenbaum 2008).

Language

In language learning a difficult problem is to work out what is and is not grammatical, and this is another problem for which too few examples exist to uniquely determine the answer (Gold 1967). Learning grammaticality is difficult: while people almost always observe only correct examples of language use, they learn both grammatical rules and also the exceptions to the rule. An example of this is the dative alternation: for most verbs it is grammatical to alternate between the

constructions “He threw the ball to me” and “He threw me the ball,” but an exception is the verb *carried* (Baker 1979).

While the absence of observing “He carried me the ball” is not proof that this construction is ungrammatical (it could be just rarely employed), it is evidence for the hypothesis that *carried* is an exception. By adjusting the weights on the hypotheses given the observed data, Bayesian models of language are able to make sensible inferences despite uncertainty about how language should be represented (Perfors et al. 2010).

Definition

Collations of Connectivity Data on the Macaque Brain (CoCoMac) is a database that contains the results of hundreds of publications in which tracer substances are injected into macaque brains to

reveal the afferent and efferent projections of neurons in the injection zones. The goal is to get complete coverage of the brain, so that a full axonal projection matrix can be extracted from the database.

The injected tracer substances diffuse from the extracellular space into the neurons and are then driven by active transport mechanisms toward the axon terminals (anterograde tracer) or toward the soma (retrograde tracer). For each tracer injection, the core information to record is (i) the location of the injection zone, (ii) whether the tracer is anterograde or retrograde, (iii) which locations in the brain are labeled by the tracer after the incubation period, and if available (iv) the laminar distribution of labeled sites and (v) quantitative measures.

This information is collated from the literature by manually parsing figures and textual statements, in which locations are expressed as brain region names. What makes the task challenging is that the relevant literature spans many decades and that nomenclatures and brain parcellations (atlases) vary widely both in time and across research groups. CoCoMac uses transformations based on spatial relations (Stephan et al. 2000) to map data onto a user-specified set of brain regions.

Collision Avoidance Models, Visually Guided

Damián Oliva
Departamento de Ciencia y Tecnología,
Universidad Nacional de Quilmes, CONICET,
Buenos Aires, Argentina

Definition

Visually guided collision avoidance models (VGCAMs) describe the operation of sensory

and motor neuronal circuits detecting potential collisions and producing motor avoidance responses. To describe these sensory–motor transformations, VGCAMs usually begin as phenomenological descriptions of responses and then focus on the study of associated neural circuits and biophysical mechanisms. At the sensory level, several biophysical processes operate in parallel to shape and tune the visual response of collision detecting neurons. VGCAMs also generate descriptions about the operation of intermediate circuits linking sensory input and motor output, when experimental data about these intermediate circuits is incomplete.

Detailed Description

Visually Guided Collision Avoidance Behaviors

Most visual animals are highly effective at detecting and avoiding collisions, which may occur either by encounters with obstacles during navigation (Tammero and Dickinson 2002b) or by moving objects that directly approach them (e.g., predators; Rind and Simmons 1999; Gabbiani et al. 2004; Simmons et al. 2010; Fotowat and Gabbiani 2011; Card 2012). In both cases, an important visual cue to predict a potential collision is the expansion of the approaching surface or object. The detection of this visual cue triggers motor programs controlled by neural circuits to generate quick and reliable avoidance responses. To be effective, the associated maneuvers need to be executed in a timely and accurate manner, which implies that the approaching object must be precisely monitored in real time. For this reason, most animals possess movement detector neurons specially tuned to detect objects approaching on a collision course. Thus, visually guided collision avoidance behaviors (VGCABs) provide a favorable model for studies of sensory coding and sensory–motor transformations.

Looming Stimuli

To describe the visuomotor transformation that begins in sensory neurons and ends in the animal's muscles, one needs well-controlled stimulation

conditions. If we stimulate the animal monocularly, approaching objects can be simulated using their two-dimensional projection on a computer screen (Gabbiani et al. 1999). Such *looming stimuli* usually represent dark circles or squares of various sizes approaching at constant speeds on a direct collision course with the animal (Fig. 1a). Let l denote the object half-size and x the object position with respect to the animal eye, i.e., $x > 0$ before collision, and $x = 0$ at collision. Defining $t = 0$ as the time of expected collision and $t < 0$ as the time before collision, the position of an object approaching at constant velocity v is described by the equation:

$$x(t) = v \cdot t. \quad (1)$$

According to these conventions, the velocity v is negative, reflecting the fact that the object is approaching. The angular size of the object at the retina, $\theta(t)$, is given by

$$\theta(t) = 2 \cdot \tan^{-1} \frac{l}{v \cdot t}. \quad (2)$$

The square drawn on the monitor screen (Fig. 1a) has a half-size, $l_{\text{screen}}(t)$, that depends

on the distance from the monitor to the eye of the animal, $x_{\text{eye-screen}}$, and the angular size, $\theta(t)$, as

$$l_{\text{screen}} = x_{\text{screen-eye}} \cdot \tan(\theta(t)/2). \quad (3)$$

The angular edge velocity of the object, $\psi(t)$, is defined as

$$\psi(t) = \frac{1}{2} \frac{d\theta}{dt} = \frac{\theta(t)'}{2} = \frac{l/v}{(l/v)^2 + t^2}. \quad (4)$$

As follows from Eqs. 2 and 4, the optical variables $\theta(t)$ and $\psi(t)$ are nonlinear functions of time and depend only on the ratio $l/|v|$ between the object's half-size l and its approach speed v . For a given object size, a faster approach speed implies a faster expansion rate and a smaller $l/|v|$ ratio. Varying the $l/|v|$ ratio thus allows investigators to manipulate the temporal dynamics of the looming stimulus.

For the stimulus to be uniquely determined by the parameter $l/|v|$, simulations must begin from an angular size smaller than the minimum one detected by the animal. If the object starts from a higher angular size, the initial angular size, θ_0 , is another independent parameter characterizing the stimulus (Oliva and Tomsic 2012).

Collision Avoidance Models, Visually Guided, Fig. 1 Looming stimuli. (a) Simulation of an object's approach at constant speed. The eye of the animal is stimulated from the left side by simulating squares of half-size l approaching at a constant speed v towards the center of the eye. The figure shows the virtual object at two different times during the simulated approach. $x(t)$ is the

position of the object in a reference system centered at the animal's eye, $\theta(t)$ is the angle subtended by the object at the animal's eye, and l_{screen} is the square half-size on the monitor screen. (b) Time course of $\theta(t)$ and of the angular edge velocity $\psi(t)$ as a function of time before collision for an approach with $l/|v| = 479$ ms and $\theta_0 = 3.9^\circ$. Both functions are nonlinear in time; see Eqs. 2–4

VGCABs in Invertebrates

Invertebrates are important models for the neurobiology of visually guided behaviors due to their accessible nervous systems and easily quantifiable behavioral output (Reichardt et al. 1983; Egelhaaf et al. 1989; Borst and Haag 2002; Srinivasan and Zhang 2004). Phenomenological descriptions usually rely on input–output functions assuming that the *motor output* is regulated by an *input optical variable*. The input optical variable may, for example, be the angular size of the object, $\theta(t)$, or its time derivatives like the angular velocity, $\theta'(t)$, or the angular acceleration, $\theta''(t)$ (Fig. 1b). A simple but useful such variable is time-to-contact, $\tau(t)$, which can be computed when θ is small and when the approach velocity is constant: $\tau \sim \theta(t)/\theta'(t)$. Time-to-contact gives a running estimate of the time before collision that could trigger a motor reaction at a constant delay prior to the anticipated collision (Gibson 1958; Lee and Reddish 1981; Wagner 1982; Wang and Frost 1992).

Invertebrate VGCABs vary considerably depending on the animal's motor system, locomotion mode, and living environment. Some VGCABs can be described as all-or-none threshold responses, triggered when an optical variable exceeds a certain value, after which the animal displays a pre-programmed motor response. This type of VGCAB was described in the crayfish defensive reflex (Glantz 1974a) and in flies (leg extension reflex for landing, Borst and Bahde 1988; Tammero and Dickinson 2002a; saccades in free flight, Tammero and Dickinson 2002b). Other avoidance responses are continuously adjusted to account for modifications of the trajectory and/or velocity of obstacles and predatory attacks. Such behaviors have been studied in the context of animal navigation (e.g., Srinivasan and Zhang 2004) and less frequently in the context of predator avoidance (Land and Layne 1995; Oliva and Tomsic 2012). Finally, there are behaviors where the avoidance response is composed of distinctive preparatory stages, each one being triggered when an optical variable reaches a particular threshold. Examples of such multistage responses are observed in locusts (e.g., Santer et al. 2005b; Fotowat and Gabbiani 2007; Fotowat et al. 2011),

flies (Card and Dickinson 2008; Fotowat et al. 2009), and crabs (Nalbach 1990; Hemmi and Pfeil 2010).

Figure 2 illustrates behavioral responses to looming stimuli in invertebrates. They exemplify ballistic-like, regulated, and multistage responses in systems where neural and behavioral analyses have been carried out.

Ballistic-Like Escape Behaviors: Fig. 2a shows a device designed to study the collision avoidance and landing responses to looming stimuli in *Drosophila* (Tammero and Dickinson 2002a). Tethered flies were placed inside an arena in which stimuli of varying trajectories and angular rates of expansion were applied (ψ constant for each stimulus). Flies have two types of responses to these stimuli: leg extensions, which are typical of the “landing response,” and a change in their wing-stroke amplitude, characteristic of collision avoidance responses. An expanding stimulus elicits both landing and collision avoidance responses, but two different pathways appear to mediate the reactions. The azimuthal position of the stimulus affects the probability of the two behaviors: the probability of the landing response is greater when stimuli are applied frontally, while the probability of a collision avoidance reaction is strongest laterally. Both the latencies and sensitivities of the two responses differ as a function of the angular velocity of expansion.

These experiments and knowledge about motion-detection circuits in flies have inspired a computational model to describe collision avoidance and landing responses (Fig. 2b). According to this model, the fly estimates optic flow during flight using a two-dimensional array of Reichardt motion detectors (Fig. 2bi) (Borst and Egelhaaf 1989). The motion information is pooled such that image expansion in the two lateral fields and in the frontal fields of view is calculated (Fig. 2bii). The outputs of these three expansion calculations are then temporally integrated and passed through threshold detectors (Fig. 2biii–iv). Expansion detected laterally triggers a collision avoidance response in the opposite direction, while frontal image expansion causes a landing response. Note that lateral expansion on one side inhibits the opposite expansion-detecting pathway,

Collision Avoidance Models, Visually Guided, Fig. 2 VGCAB in invertebrates. (a) Schematized experimental setup for measuring a fly's response to image expansion. During tethered flight, the fly's wing-stroke amplitude and frequency are measured by optically tracking the shadows cast from an infrared (IR) diode by each of the wings on an optical wing-beat analyzer. The difference between the amplitudes of each wing stroke controls the visual display, allowing the fly to orient actively towards the position of the $15^\circ \times 15^\circ$ square. At periodic intervals, the square symmetrically expands, eliciting a behavioral

response. (Adapted from Tammero and Dickinson (2002a)). (b) Computational model to describe collision avoidance and landing responses in flies. (See text for details; Adapted from Tammero and Dickinson (2002a)). (c) Measurement of the escape response in the crab *Neohelice granulata*. Locomotor activity was studied in a walking simulator consisting of a Styrofoam ball that could be freely rotated by the animal. The crab was held in position by a weightless rod attached to its carapace that could slide up and down within a guide located above the animal. Locomotion was assessed by recording the

preventing a turn from being immediately followed by another one in the opposite direction (Fig. 2bv).

Other insects, such as locusts, also present collision avoidance responses during flight. When looming stimuli are presented, flying locusts may, for example, produce a gliding behavior to evade aerial predators (Santer et al. 2005a).

Continuously Regulated Escape Behaviors: Fig. 2c shows a system designed to study collision avoidance responses to looming stimuli of initial size θ_0 in the crab *Neohelice granulata* (Oliva et al. 2007). The escape response consists of a threshold-type decision for initiating the escape run, followed by a visually regulated mechanism for continual control of the escape speed (Oliva and Tomsic 2012). The escape decision and the regulated speed mechanism can be described by a phenomenological input–output function f_{IO} that describes the crab speed, $v_c(t)$, as a function of an optical variable, $u_2(t - \delta)$, evaluated δ milliseconds earlier:

$$\begin{aligned} v_c(t) &= f_{IO}[u_2(t - \delta)] \text{ if } u_2 \\ v_c(t) &= 0 \text{ if } u_2(t - \delta) \leq 0. \end{aligned} \quad (5)$$

The optical variable $u_2(t)$ is the product of the angular increment since the onset of expansion, $\Delta\theta(t) = \theta(t) - \theta_0$, and of the stimulus angular velocity, $\theta'(t)$:

$$u_2(t) = (\Delta\theta(t) - \Delta\theta_{esc}) \cdot \theta'(t). \quad (6)$$

The parameter $\Delta\theta_{esc}$ is a threshold independent of looming stimulus dynamics. In addition to regulating the speed of escape (Eqs. 5 and 6), the crab makes continuous adjustments to the escape

direction as a function of the path of the object approach (Land and Layne 1995). Thus, the predator is maintained laterally and the crab runs in the opposite direction.

Multistage Escape Behaviors: Fig. 2d shows a looming-evoked multistage escape behavior in locusts (Santer et al. 2005b; Fotowat and Gabbiani 2007). The locust jump consists of several distinct phases, during which the animal orients itself away from the approaching object using its middle legs and stores the energy required for takeoff in the elastic elements of its hind legs (Heitler 1974; Burrows 1996). By monitoring the position of the hind leg femur–tibia joint, Fotowat and Gabbiani (2007) showed that after an initial flexion of the tibia, the joint moves to align the leg parallel to the body. This stage is called the *initial joint movement* (IJM). Subsequently, the flexor and extensor muscles of the hind legs contract simultaneously to store the mechanical energy required for the jump, a stage known as *co-contraction*. This leads to a *final femur–tibia joint movement* (FJM), which is followed by cessation of activity in the flexors, also known as *triggering*. After this, the energy accumulated in elastic hind leg elements is released and *takeoff* occurs.

Figure 2e shows a linear relationship between the mean takeoff time and the value of the looming stimulus parameter $l/|v|$. This linear relationship is equivalent to takeoff occurring with a fixed offset relative to the time the stimulus has reached a fixed angular threshold size on the retina (Gabbiani et al. 1999). Fotowat and Gabbiani (2007) studied the execution times for the IJM and FJM, also showing a linear relationship for t_{IJM} and t_{FJM} as a function of $l/|v|$. Thus, the initial

Collision Avoidance Models, Visually Guided, Fig. 2 (continued) rotations of the ball with two computer mice. The looming stimuli were applied from the right. (Adapted from Oliva and Tomsic (2012)). (d) Looming-evoked multistage escape behavior in locust. Drawing of four frames of a looming stimulus with $l/|v| = 60$ ms. *Frame 1* corresponds to the first stimulus frame. *Frames 2* and *3* correspond to the average timing of the first two preparatory stages of the jump escape behavior (*IJM* and *FJM*; see

main text). The last frame corresponds to the average timing of takeoff [time to collision (tc) is negative before takeoff]. (Adapted from Fotowat and Gabbiani (2007)). (d) Mean timing of takeoff and SD relative to expected collision (time remaining to collision positive before expected collision). Locusts were presented looming stimuli at $l/|v| = 40, 60, 80, 100$, and 120 ms (n indicates number of jumps recorded across all animals. (Adapted from Fotowat and Gabbiani (2007))

and final preparatory phases and takeoff are triggered when the approaching object crosses successive threshold angular sizes on the animal's retina. A similar study conducted for the jumping escape response of *Drosophila melanogaster* to looming stimuli found again a linear relationship between the mean takeoff time and $l/|v|$ (Fotowat et al. 2009).

Another important aspect of visually guided jumping escape responses is related to the control of the escape's direction. Using high-speed videography, Santer et al. (2005b) showed that, after the start of co-contraction, locusts produce tilting postural movements mediated by the pro- and mesothoracic legs. These movements rotate the long axis of the locust towards the direction of jump up to 50° to either side of their long axis. In addition, escape circuitry allows locusts to control the timing, distance, and elevation of these jumps (Santer et al. 2005b; Simmons et al. 2010).

In another series of studies on escape's directionality, Card and Dickinson (2008) described the escape behavior of the fruit fly, *Drosophila*, showing that the fly's escape response is composed of different stages occurring while the object is approaching: (1) freeze, (2) a body lean or leg postural adjustment, (3) wing elevation, and (4) jump. They found that flies can use visual information to plan a jump directly away from a looming threat by a series of postural adjustments that determine the direction of their escape. This is accomplished by regulating the position of their center of mass in relation to the middle leg points of contact. Thanks to this strategy, the extension of the middle legs pushes them away from the expanding visual stimulus.

Collectively, the results from these studies suggest that the invertebrate central nervous system is capable of mapping particular azimuthal positions in visual space to a set of trajectories in motor space. Furthermore, it was proposed that independent descending pathways with different thresholds of activation regulate these visuomotor transformations (Santer et al. 2008; Card and Dickinson 2008; Card 2012).

These behavioral data raise the question: What information do visual neurons encode to regulate these VGCABs? In the next section, we describe a

set of neurons specially tuned to detect stimuli on a collision course. These neurons are important elements of the descending pathways that regulate VGCABs.

Looming-Sensitive Neurons in Invertebrates

Neurons tightly tuned to detect objects approaching on a direct collision course, called looming-sensitive neurons (LSNs), have been characterized in locusts (Schlotterer 1977; Rind and Simmons 1992; Gabbiani et al. 1999; Gray et al. 2010), flies (Borst 1991; Fotowat et al. 2009), praying mantis (Yamawaki and Toh 2009), crayfish (Glantz 1974a), and crabs (Medan et al. 2007; Oliva et al. 2007).

The most important property of LSNs is their preferential response to looming rather than to receding or translating stimuli. For example, Fig. 3a shows the response to looming and receding stimuli of the motion detector neurons MLG1 and MLG2 in the crab *Neohelice granulata*. Both stimuli have the same value of $l/|v|$ and therefore act on the same number of photoreceptors but with a temporarily reversed photoreceptors' activation dynamics. As seen in the figure, the response to expansion is much larger than that to contraction.

In contrast to neurons involved in optomotor response behaviors, such as those broadly studied in the fly (Borst and Haag 2002), LSNs have a weak response or are inhibited by whole field motion (Rind and Simmons 1992; Gabbiani et al. 2002; Medan et al. 2007). Furthermore, LSNs do not have a strong directional sensitivity across their visual field (Krapp and Gabbiani 2005; Medan et al. 2007), respond to small object movement, and have large receptive fields (Rowell et al. 1977).

Some LSNs exhibit adaptation processes inhibiting their response to stimuli that are constant over time. This phenomenon generates selectivity to looming stimuli (which produce a temporal increase in excitation), as opposed to translating movements that produce constant excitation (Peron and Gabbiani 2009b, c).

Another phenomenon observed in many LSNs is the reduction of their responses to repetitive stimulation (known as habituation; Glantz 1974b; O'Shea and Rowell 1975; Tomsic et al.

Collision Avoidance Models, Visually Guided, Fig. 3 Response of crabs' MLG1 and MLG2 neurons to looming and receding stimuli. (a) Responses to a black looming and receding stimulus for MLG1 neurons. (b) Same as (a) for MLG2 neurons. Sample recordings from a single MLG1 and a single MLG2 neuron illustrate the type of responses of these neurons. Peristimulus time

histograms show the mean spike rate recorded from 11 MLG1 and 13 MLG2 neurons from different animals (one trial per stimulus per neuron). Data is subdivided into 100 ms bins and is plotted as mean $\pm$ s.e.m. The angular size of the looming and receding object is given in the bottom traces of each panel. Arrowheads signal the beginning of the stimulus. (Adapted from Oliva et al. (2007))

2003; Gray 2005). This property is expected, since if these neurons are an important part of the warning and escape system, the animal must have mechanisms to protect against repetitive stimulation that is harmless. Furthermore, LSNs must possess mechanisms to avoid habituation to wide-field motion stimuli experienced during locomotion; lateral presynaptic inhibition is thought to represent one such mechanism (O'Shea and Rowell 1975).

How do sensory circuits encoding looming stimuli work and what are the biophysical processes tuning LSNs to looming stimuli? To date, the most complete answers to these questions have been obtained in the lobula giant motion detector (LGMD) neuron of the locust. In the following section, we will see that various biophysical processes work in parallel to shape its visual responses.

LGMD/DCMD Neurons in Locust

The lobula giant motion detector (LGMD) is an identified neuron in the third visual neuropil of the

locust optic lobe (lobula) that responds vigorously to objects approaching on a collision course (Fig. 4). The locust LGMD is an extensively studied looming-sensitive neuron (O'Shea and Rowell 1976; Rowell et al. 1977; Schlotterer 1977; Rind and Simmons 1992; Hatsopoulos et al. 1995; Judge and Rind 1997; Gabbiani et al. 1999, 2002; Krapp and Gabbiani 2005; Guest and Gray 2006; Santer et al. 2008; Peron et al. 2009; Peron and Gabbiani 2009a, b; Fotowat and Gabbiani 2011; Jones and Gabbiani 2012b). It makes a strong synapse with another identified neuron, the descending contralateral movement detector (DCMD; Rowell 1971; O'Shea and Williams 1974). The synaptic contact between the LGMD and the DCMD is so powerful that LGMD's spikes are transmitted in a 1–1 manner to the DCMD. Thus, under visual stimulation, each spike in the DCMD is caused by a spike in the LGMD. The DCMD large axon travels down the animal's contralateral nerve cord and contacts motor and interneurons involved in generating jumps and flight steering (Burrows and Rowell

Collision Avoidance Models, Visually Guided, Fig. 4 Schematics of LGMD circuitry. The lobula giant movement detector (LGMD) receives excitatory synaptic inputs (circles shaded in dark gray) on a large dendritic field (A). An important characteristic of this pathway is the presence of a lateral inhibitory network between excitatory afferent fibers presynaptic to the LGMD (inhibitory synapses are illustrated by circles shaded in light gray). ON and OFF feedforward inhibition impinges on two separate dendritic fields (B and C, respectively). The LGMD makes a strong synapse with the descending contralateral movement detector (DCMD) that contacts motor and interneurons involved in generating jumps and flight steering. (Adapted from Gabbiani et al. (2005))

1973; O'Shea et al. 1974; Simmons 1980). Therefore, the LGMD/DCMD neurons provide an excellent system for studying the sensory-motor transformations that occur during looming-evoked collision avoidance behaviors (Fotowat and Gabbiani 2011).

As in many LSNs, the LGMD responds to the movement of small objects irrespective of the object's location in the neuron's receptive field. This response is small and weakly directionally selective. The neuron is also inhibited by whole field motion and, as previously mentioned, it is vigorously excited by objects approaching on a collision course with the animal (Schlotterer

1977; Rind and Simmons 1992; Hatsopoulos et al. 1995; Gabbiani et al. 1999).

The LGMD neuron has three dendritic subfields that integrate different processes (O'Shea and Williams 1974). The main subfield (A) receives ~15,000 cholinergic excitatory synapses arranged retinotopically. The remaining two dendritic subfields (B and C) receive ~1000 feedforward GABAergic inhibitory synapses (Rowell et al. 1977; Gabbiani et al. 2005). Current evidence is consistent with subfields B and C providing phasic ON and OFF inhibition, respectively (Gabbiani et al. 2004).

Figure 4 shows a proposed model for the LGMD/DCMD circuit (Rowell et al. 1977; Rind and Bramwell 1996; Gabbiani et al. 1999). In this model, excitatory presynaptic inputs arriving at dendritic subfield A experience lateral inhibition (LI) that reduces LGMD responses to wide-field stimuli. On the other hand, there are also feedforward inhibitory (FFI) processes acting on subfields B and C, which increase with the size of the moving object, generating the selectivity of this neuron to small object movement and controlling the rapid saturation to looming stimuli.

LGMD/DCMD Responses to Looming Stimuli

Figure 5a shows the typical response of the LGMD neuron to looming stimuli as the looming parameter $l/|v|$ is varied over one order of magnitude (5–50 ms; Gabbiani et al. 1999). The overall time course of the LGMD's firing rate consists of an increase followed by a peak and a subsequent decrease. A feature of the LGMD response to looming stimuli is that the peak firing time consistently shifts towards collision as the parameter $l/|v|$ is reduced. Plotting peak firing time relative to collision, t_{peak} , as a function of $l/|v|$ reveals a relation that can be fitted by a linear function with slope, α , and intercept, δ (Fig. 5b). Thus, the LGMD's peak firing time acts as an *angular threshold detector*, signaling, with a delay of δ ms, the time at which an object reaches a fixed angular size $\theta_{thres} = 2 \tan^{-1}(1/\alpha)$ on the retina (Fig. 5a; Gabbiani et al. 1999).

Using data from electrophysiological and anatomical characterizations of the LGMD (Palka 1967; Rowell et al. 1977) and the linear relation

Collision Avoidance Models, Visually Guided, Fig. 5 LGMD response to looming stimuli. (a) Peak firing rate signals that an angular threshold was exceeded δ ms earlier. The time course of angular size is depicted in the top panel for three approaches at different values of $l/|v|$. The mean angular size subtended by the object δ ms prior to the peak for each approach is indicated by the crosses. The corresponding time course of the instantaneous firing rate is illustrated in the bottom three panels

(with each panel corresponding to a different value of $l/|v|$). The position of the peak firing rate is indicated by the dotted lines while the dashed lines indicate the moment in time preceding the peak by δ ms. Note that the value of θ_{thres} is independent of $l/|v|$, as read from the ordinate θ_{thres} on the top panel. (b) Relation between the time of peak firing rate and $l/|v|$ is linear. The parameters δ and θ_{thres} are obtained from the linear fit (see inset). (Adapted from Gabbiani et al. (1999))

from Fig. 5b, Gabbiani et al. (1999) proposed an input-output function, f , describing the firing rate of the LGMD and DCMD neurons that should satisfy the following three assumptions: (1) f should depend only on the angular size $\theta(t)$ and angular edge velocity $\psi(t)$ of the approaching object. These two variables are thought to be represented in the form of inhibitory (size-dependent) and excitatory (motion-dependent) inputs to the various dendritic subfields of the LGMD. (2) The firing rate at time t depends only on the value of θ and ψ at time $t - \delta$. (3) The peak of $f(t)$ should satisfy the linear relation between t_{peak} and $l/|v|$ shown in Fig. 5b. These assumptions

imply that f must be described by the following phenomenological model:

$$f(t) = g\left(\psi(t - \delta) \cdot e^{-\alpha \cdot \theta(t - \delta)}\right), \quad (7)$$

where $g(\eta)$ is a static nonlinearity that characterizes the transformation between the kinematic variable $\eta = \psi(t - \delta) \cdot e^{-\alpha \cdot \theta(t - \delta)}$ equation and the firing rate.

Gabbiani et al. (2001) investigated the dependence of this angular threshold computation on several stimulus parameters that alter the spatial and temporal activation patterns of inputs of the LGMD. It was shown that the same angular

threshold computation was implemented by the LGMD in three different locust species and that the computation was invariant to changes in target shape (from solid squares to solid discs), to changes in target texture (checkerboard and concentric patterns), and to changes in contrast (Gabbiani et al. 1999). Finally, the angular threshold computation did not depend on object approach angle, over at least 135° in the horizontal plane.

These findings raise the question: How does the LGMD implement the multiplicative operation between angular edge velocity ψ and angular size θ in Eq. 7? The proposed scheme is based on excitation being logarithmically related to angular velocity and added to inhibition signaling angular size, followed by an approximate exponentiation at the spike initiation zone (SIZ) that converts membrane voltage to firing rate (Gabbiani et al. 2002). Together, these steps result in a multiplication of the excitatory and inhibitory inputs to the LGMD, as summarized in Eq. 8:

$$f(t) = g[\exp[\log(\psi(t - \delta)) - \alpha \cdot \theta(t - \delta)]]. \quad (8)$$

The model of Eqs. 7 and 8 accurately describes the LGMD/DCMD firing rate around the time of maximum activity (t_{peak}). However, for the prediction to be accurate at all times, it is necessary to relax the second assumption and add a dependency to the static nonlinearity g , with respect to the parameter $l/|v|$ (Gabbiani et al. 1999):

$$f(t) = g_{l/|v|}[\psi(t - \delta) \cdot e^{-\alpha \cdot \theta(t - \delta)}]. \quad (9)$$

This dependence of the g on $l/|v|$ is attributable both to the properties of the conductances shaping the response of the LGMD and to its presynaptic elements that were not taken into account in the derivation of Eqs. 7 and 8 (Gabbiani et al. 1999). Although the proposed computation (Eqs. 7–9) has a high predictive power and provides insight into the LGMD computation, we will see next that many biophysical processes act in parallel to shape and tune the LGMD response to looming stimuli.

Experimental Characterization and Computational Modeling of Presynaptic Circuitry and Feedforward Excitation to the LGMD Subfield A

The LGMD receives retinotopic excitatory input from an entire visual hemifield (see Figs. 4 and 6a). Using electrophysiology, in vivo imaging, and pharmacology, it has been shown that this excitatory projection activates calcium-permeable nicotinic acetylcholine receptors and preserves retinotopy down to the level of a single ommatidium (Peron et al. 2009). Figure 6bi shows the proposed mechanism that results in speed sensitivity of the LGMD's excitatory input (Jones and Gabbiani 2010). When a translating edge stimulus is applied, the figure's edges move with angular velocity ψ through the array of facets on the animal's eye (Fig. 6ai). The faster the movement of a dark edge across a facet (Fig. 6bi), the more rapidly the luminance encountered by the underlying photoreceptors will decrease (Fig. 6bii). More specifically, an edge traveling at a constant speed ψ , and sweeping through a Gaussian receptive field of width σ_x , will produce a local, time-dependent luminance change that has the functional form of a cumulative Gaussian with a duration determined by its standard deviation (SD), $\sigma_t = \sigma_x/\psi$. Below photoreceptors, the most likely next stage in the visual pathway is the large monopolar cells (LMCs) in the lamina (Fig. 6aii; James and Osorio 1996; Rind and Bramwell 1996). Recordings from LMCs revealed that these neurons responded to these luminance changes with increasing depolarization proportional to $1/\sigma_t$, yielding a local response proportional to the stimulus speed $\psi = \sigma_x/\sigma_t$ and consistent with the high-pass filtering properties reported in other insect species (Laughlin and Hardie 1978). Another effect was that the latency of the peak response in LMCs cells decreased as the stimulus duration became shorter (or as the edge velocity was increased).

Because recording from the transmedullary neurons that synapse onto the LGMD is not yet technically feasible, Jones and Gabbiani (2010) measured the effect of that stage of the excitatory pathway by voltage clamping the LGMD to resolve excitatory postsynaptic currents elicited by single-facet stimulation (Fig. 6aiii–iv).

Collision Avoidance Models, Visually Guided, Fig. 6 Circuitry, physiology, and modeling of the excitatory presynaptic circuit to the LGMD. (a) Recordings from photoreceptors, LMCs, and the LGMD in both voltage (I_m) and current (V_m) clamp to single-facet stimuli (right, cyan traces) enable analysis of how edge speed is coded along the pathway. Five facets on the eye (top, dashed square) mapped onto five distinct locations within the excitatory dendritic field (matching square and hues) symbolize its retinotopic organization. (ai) Photoreceptors (Ph) hyperpolarize (right, cyan trace) as dark edges cross their receptive fields over single facets on the eye (top, yellow circles). (aai) Subsequently, that information propagates along an excitatory pathway comprising LMCs and medullary interneurons (Med), terminating onto the

LGMD's large excitatory dendritic field (green rake). (iii–iv) Voltage and current clamping the LGMD to resolve postsynaptic currents. In addition, the LGMD receives inhibition related to stimulus size onto distinct dendrites (red line). (b) Model of velocity encoding by single photoreceptors and its relation with the LGMD excitatory synaptic conductance's strength and latency. (bi) As a dark object crosses the Gaussian-shaped receptive field, it produces a luminance (Lum) change whose duration depends on stimulus speed (bii). (biii) The luminance change duration ($LD = 4 \cdot \sigma_t$) and the edge velocity ψ determine the LGMD excitatory synaptic conductance's strength and latency (biv). (Adapted from Jones and Gabbiani (2010, 2012b))

Based on these experiments, Jones and Gabbiani (2012b) described the excitatory synaptic conductance's strength and latency as a function of the edge velocity ψ and of the luminance change duration ($LD = 4 \cdot \sigma_t$), respectively (Fig. 6biii).

To construct a computational model of the LGMD excitatory current to looming stimuli, it is necessary to incorporate information about the spatial distribution of ommatidia on the locust eye (Krapp and Gabbiani 2005). Based on this information, the luminance input to each facet can be calculated as a function of time, and, using the model for the excitatory conductance (Fig. 6biii–iv), the excitatory postsynaptic current in the

LGMD compartment associated with facet number n , $i_{exc,n}$, is described by

$$i_{exc,n}(t) = g_{exc,n}(t) \cdot (V_n(t) - E_{exc}), \quad (10)$$

where $V_{dend,n}$ is the dendritic compartment potential in the region associated to the facet, E_{exc} is the excitatory synaptic reversal potential, and $g_{exc,n}$ is the excitatory conductance (current and conductance are expressed per unit area).

Finally, another effect related to the latency reduction for faster luminance changes, defined as the synchronization effect, was characterized in the LGMD (Jones and Gabbiani 2010). By selectively stimulating an array of neighboring

photoreceptors, latency reduction (Fig. 6biii) favors summation of inputs activated sequentially throughout the looming sequence, making the neuron maximally sensitive to looming stimuli. Therefore, the LGMD's selectivity arises partially from presynaptic synchronization of a large population of inputs during a looming stimulus and subsequent postsynaptic detection within the LGMD neuron.

Experimental Characterization of Lateral Inhibition (LI) and Feedforward Inhibition (FFI) in LGMD to Looming Stimuli

To analyze separately the action of LI and FFI, Rowell et al. (1977) conducted intracellular recordings between dendritic field A and the LGMD's SIZ. When measuring membrane voltage in this region, IPSPs associated with the FFI could be observed to evaluate their effect on the LGMD firing rate.

Through this approach, it was shown that LI or FFI can be selectively activated with a translating square-wave grating stimulus. If the grating has wavelength λ and angular velocity ω , the contrast frequency is defined as $fc = \omega/\lambda$. For contrast frequencies below 12 Hz, there was a reduction in the LGMD firing rate, but no IPSPs were observed. In this range of frequencies, the grating stimulus preferentially activates presynaptic LI. For frequencies greater than 12 Hz, IPSPs were observed, which indicated the activation of FFI.

A subsequent experiment was designed to analyze the influence of LI on looming stimuli (Gabbiani et al. 2002). In this experiment, looming and a low-frequency wide-field drifting grating were simultaneously applied. As indicated above, LI was thus preferentially activated. By comparing the difference between the response to this stimulus and the response to a looming stimulus alone, it was shown that the effect of LI was mainly produced for angular sizes $\theta < 23^\circ$.

As we saw earlier, the phenomenological model (Eqs. 7–9) assumes that inhibition depends on the angular size, $\exp(-\alpha \cdot \theta)$, and is mainly produced by FFI on LGMD's dendritic fields B and C. To test this hypothesis experimentally, FFI was inactivated through the local application of a GABA antagonist (picrotoxin) in these

dendritic subfields (Gabbiani et al. 2002, 2005). After blocking feedforward inhibition by means of picrotoxin injection, the duration of LGMD responses to looming stimuli was greatly prolonged. This manipulation also increased the number of spikes and peak firing rates relative to control trials. These results suggested that feedforward inhibition plays an important role in controlling feedforward excitation. Based on these experimental results, it was concluded that the multiplicative operation is most likely caused by the interaction between postsynaptic feedforward excitation and inhibition within the LGMD itself, rather than through presynaptic inhibition.

Although LI does not have a significant influence on the LGMD response to looming stimuli for angles greater than 23° , this inhibition is important to protect the LGMD against habituation to visual stimuli that the animal experiences while walking or flying (O'Shea and Rowell 1975). Furthermore, it can strongly influence the response of this neuron to the movement of small stimuli (Rind and Simmons 1999; Peron and Gabbiani 2009b). A biologically inspired computational model of LI was developed in Rind and Bramwell (1996).

Spike-Frequency Adaptation Process and Its

Influence in the LGMD Tuning to Looming Stimuli Another biophysical process that affects the tuning of the LGMD to looming stimuli is spike-frequency adaptation (SFA). SFA is a reduction of a neuron's firing rate to a stimulus of constant intensity. The LGMD exhibits rapid adaptation to both constant current injection (Gabbiani and Krapp 2006) and to translating objects moving at constant angular speed (Peron and Gabbiani 2009a, b). Using pharmacology and Ca^{2+} imaging techniques, Peron and Gabbiani (2009a) showed that SFA is mediated by a Ca^{2+} -dependent K^+ current I_{AHP} governed by a large influx of calcium in the region between the spike initiation zone (SIZ) and the excitatory dendritic field (see Fig. 6a). Intracellular block of this current minimally affected the LGMD's response to looming stimuli but substantially increased its response to translating ones. Thus, SFA contributes to the

neuron's tuning by selectively decreasing its responses to non-preferred stimuli, such as translating and receding stimuli (Peron and Gabbiani 2009b). Peron and Gabbiani (2009a, b) constructed a computational model with three compartments that simulate the dendrites, the region where I_{AHP} was localized, and the axon. This computational model could explain several aspects of the LGMD responses to visual stimuli, current pulses, and pharmacological treatments (Peron and Gabbiani 2009a). Furthermore, it was shown that SFA acts as a selectivity filter for specific temporal input profiles. In the context of time-varying stimuli, adaptation is least effective at suppressing spikes in response to stimuli where not only the first but also the second derivative of the input's intensity is positive. Looming stimuli exhibit precisely this property, and this may explain the insensitivity of the LGMD's looming response to SFA. In conclusion, SFA provides an example of how a membrane conductance can tune a neuron for specific time-varying stimuli (Peron and Gabbiani 2009b).

Computational/Biophysical Model of LGMD Response to Looming Stimuli

The biophysical processes involved in the LGMD computation described phenomenologically (Eqs. 7–9) could be understood in a detailed computational/biophysical model (Jones and Gabbiani 2012b). The model took into account the morphology of the neuron (Peron et al. 2007) and the action of different intrinsic and synaptic currents acting on the LGMD (Fig. 6a). The model neuron had a rake-like dendritic tree, where it received excitatory synaptic inputs (see Eq. 10). It also possessed active conductances implementing realistic SFA within the SIZ. In addition to the time-varying excitatory input, the model included inhibitory inputs stimulated with a fixed magnitude and delay after the stimulus had reached each new facet. Therefore, the size-dependent inhibitory synaptic current acting on the LGMD (Fig. 6a), i_{inh} , was described by

$$i_{inh}(t) = g_{inh}(t) \cdot (V_m(t) - E_{inh}). \quad (11)$$

Here, V_m is the dendritic compartment potential, E_{inh} is the inhibitory synaptic reversal

potential, and g_{inh} is the inhibitory conductance. Due to these assumptions, the synaptic inhibition was approximately proportional to the area covered by the looming stimulus, consistent with previous descriptions of feedforward inhibition onto the LGMD (Hatsopoulos et al. 1995; Gabbiani et al. 2005). Finally, the SIZ compartment contained Hodgkin–Huxley active conductances for spike production, and synaptic noise in the model was adjusted to fit the variability of experimental data to single-facet stimulation (Jones and Gabbiani 2012a, b).

As seen in Fig. 7a and b, the model displayed looming responses similar to those observed in vivo and reproduces the linear relationship between t_{peak} and $1/|v|$ described above. But, how does the LGMD implement the logarithmic transformation of angular edge velocity ψ and the multiplication with angular size θ in Eqs. 7–9?

The biophysical/computational model addressed these questions by examining how signals at different levels of the circuit and in different compartments of the model were interrelated and how they were related to the angular speed and size of the looming stimulus. To evaluate the signal transformations in the context of the proposed computation, Jones and Gabbiani (2012b) first quantified the relationship between angular velocity, the total excitatory synaptic conductance to the LGMD model, and the dendritic and SIZ membrane voltage.

Figure 7c shows the normalized excitatory synaptic conductance and both the dendritic and SIZ V_m during looming. Because the dendritic and SIZ V_m are similar to one another, it was concluded that the velocity tuning transformation occurs locally within the dendrites of the model and that the SIZ V_m was a close reflection of the local dendritic V_m . Using the data in Fig. 7c, the excitatory conductance and resulting V_m at the SIZ were plotted against each other (Fig. 7d), and from this figure, we observe that the transformation between the two signals can be described as a logarithmic compression. The light dashed lines show logarithmic fits to the curves and the inset shows that the relationship is approximately linear when displayed on a logarithmic abscissa. To understand how the logarithmic compression

Collision Avoidance Models, Visually Guided, Fig. 7 Computational/biophysical model of LGMD response to looming stimuli. (a) Spiking responses of the LGMD model to looming stimuli. *Top* traces show the stimulus angular size for $l/|v| = 10, 40$, and 80 ms. The rasters show spiking in 50 simulated presentations for each $l/|v|$ value, and *bottom* traces show the mean instantaneous firing rates of the model computed by convolution of individual spike trains with a Gaussian filter (SD, 20 ms). Envelopes show SEM. (b) The timing of the model LGMD peak firing rate (circles, error bars show SEM) depends linearly on $l/|v|$ (black dashed line). This corresponds with the peak response occurring 14.7 ms after the stimulus has reached a constant angular size of 23.7° . The gray line shows the best fit linear relationship found in Jones and Gabbiani (2010). (c) Membrane potential over time in multiple locations. *Lighter* traces show the membrane potential over time in a dendritic compartment corresponding to the center of the visual field, while the

brighter solid traces are the V_m near the SIZ. For comparison, the time course of $g_{exc}(t)$ is plotted. (d) The relationship between $g_{exc}(t)$ and the resulting membrane potential near the SIZ. Colors show responses to different looming stimuli as in (a). *Solid lines* show the observed relationship, while *dashed lighter lines* show fitted functions of the form $V_m = A \cdot \log(B \cdot g_{exc})$. The *inset* shows the data on a logarithmic x-axis, demonstrating that the relationship is approximately linear with a slight dependence on the $l/|v|$ parameter. (e) Time course of the V_m inhibitory influence is shown, plotted with the angular size of the stimulus. Signals are all normalized to their maximum across $l/|v|$ values. (f) Instantaneous firing rate function for the model. The *solid black line* depicts the averaged relationship between median filtered SIZ V_m and IFR, while the *dotted lines* are one SD away from it. The *red dashed line* shows the best fitting power-law function. (Adapted from Jones and Gabbiani (2012b))

occurs, Jones and Gabbiani analyzed the dendritic membrane potential, concluding that the cause of the compression was due to a reduction in the driving force of synaptic excitatory currents as an increasing number of synapses are activated by the looming stimulus (see Eq. 10).

On the other hand, simulations showed that, unlike the excitatory process, the size-dependent inhibitory conductance was more subtly transformed. Since the reversal potential of inhibitory inputs were only 10 mV below the resting potential, the best way to measure the effect of inhibition on the output of the model was to consider the difference in V_m of simulations with and without inhibition; they called this difference: $V_{m\text{inhibitory influence}}$. Figure 7e shows its time evolution with the angular size of the stimulus. This time course was consistent with the feedforward inhibition observed experimentally in the firing rate of LGMD (Gabbiani et al. 2005).

The observation that the excitatory synaptic conductance activated by a looming stimulus is compressed nearly logarithmically in the membrane potential of the model, while the inhibitory influence remains much closer to signaling angular size, matches the proposed phenomenological model that excitatory and inhibitory inputs are effectively multiplied by an addition in logarithmic coordinates. The subsequent approximate exponentiation is then implemented via a non-linear transformation at the SIZ of the LGMD (Eq. 8; Gabbiani et al. 2002).

Figure 7f shows the transformation between membrane potential at the SIZ and instantaneous firing rate. This relation was fit with a power law, suggesting that this supralinear transformation plays a role similar to the exponentiation proposed in Eq. 8 (Gabbiani et al. 2002).

In conclusion, this computational model (Jones and Gabbiani 2012b) suggests a plausible biophysical implementation of the computation performed by the LGMD: the total excitatory input to the LGMD is expansively dependent on angular velocity but is logarithmically compressed by local reduction of the driving force in the dendrites, resulting in membrane potential changes that are a saturating function of velocity. In the main dendritic trunk, this excitatory signal is summed with an inhibitory signal related to the stimulus' angular size; in the biophysical model, this inhibitory influence tracks angular size sub-linearly. The resulting membrane potential is transformed by a final nonlinear, expansive spike-thresholding step at the LGMD's SIZ. The output firing rate thus reflects a multiplication between the stimulus' angular velocity and a negative exponential of its angular size.

Phenomenological Models in Other LSNs

Studies to characterize other LSNs have been carried out in different animal species. Table 1 summarizes some phenomenological models describing LSN responses to collision stimuli. These models use input–output functions of the type $R(t) = g(z(t - \delta))$, where z is an input optical variable, $R(t)$ is the neuronal firing rate, and δ is the delay time. The examples in Table 1 show that the optical variables most commonly used are the angular velocity $\theta'(t)$ and the angular size $\theta(t)$. Using this information, an animal could compute in parallel several variables of interest, such as the time to collision τ and the η function. This seems to be the case of pigeons, in which extracellular recordings in the optic tectum showed three types of neurons (called ρ , τ , and η) that encode information on collisions (Sun and Frost 1998; Laurent

Collision Avoidance Models, Visually Guided, Table 1 Phenomenological models in LSNs

Animal	Neuron	Optical variable	References
Crayfish	Jittery movement fibers	θ'	Glantz (1974a)
Locust	LGMD/DCMD	$\eta = \theta' \cdot e^{-\alpha \cdot \theta}$	Gabbiani et al. (1999)
Pigeon	Neurons η , ρ , τ	$\rho = \theta'$	Sun and Frost (1998)
		$\tau = \theta/\theta'$	
		$\eta = \theta' \cdot e^{-\alpha \cdot \theta}$	
Goldfish	Mauthner cell	$\kappa = \theta \cdot e^{-\alpha \cdot \theta}$	Preuss et al. (2006)

and Gabbiani 1998). These results indicate that the pigeon's brain reconstructs objects approaching using several computations. Each variable provides a different piece of information about the state of the environment, and the animal presumably makes an informed decision on the basis of these different inputs. Moreover, given the results of Table 1, it will be interesting to investigate whether the biophysical processes described in the LGMD neuron (see previous section) can be generalized to other species.

Linking Sensory Coding and Behavioral Responses

In recent years, significant progress has been made in understanding the function of sensory circuits and in the phenomenological description of behavioral and neuronal responses to looming stimuli. However, important aspects are still unknown about the mechanisms that nervous systems use to decide whether, when, in which direction, and how intensely to perform an escape response (Santer et al. 2008; Fotowat and Gabbiani 2011; Hemmi and Tomsic 2012; Card 2012; Herberholz and Marquart 2012).

One approach to study these issues (generally used when experimental data about intermediate circuits is incomplete) is to use VGCAMs to propose feasible descriptions about the operation of intermediate circuits linking sensory input and motor output. For example, Glantz (1974a) proposed a model for the crayfish's defensive reflex. Using the fact that crayfish LSNs encode the angular velocity of expansion (see Table 1), the existence of a firing rate integrator was proposed, such that the behavioral response was displayed when an accumulated number of spikes exceeded a threshold value. This model could explain that the behavioral response was produced when the angular size increased by a fixed value of 8° .

Another example of this approach is the computational model for eliciting collision avoidance and landing responses in flies (Tammero and Dickinson 2002a, b) (see Fig. 2b). It is noteworthy that these VGCAMs can be used to frame hypotheses about circuitry, which can be directly tested by current or future experiments.

To study experimentally how sensory information control decisions and generate different motor escape patterns, it is extremely useful to have an experimental preparation which allows the measurement of neural activity in sensory neurons and interneurons, electromyographic activity in important muscles, and behavioral response in a freely behaving animal. In this direction, Santer et al. (2008) studied looming behavior in tethered locusts walking on a ball, where locusts perform pre-takeoff leg adjustments, but do not complete the final hind leg extension for the takeoff jump. Nevertheless, using simultaneous high-speed videography and extracellular recording, it was possible to correlate DCMD responses with the timing of hind leg flexion.

Recently, a study which simultaneously measured the DCMD neuron activity, muscle activity in the hind legs, and the animal's acceleration was conducted in freely behaving locusts (Fotowat et al. 2011). It used a miniature telemetry system to transmit data output to a remote receiver wirelessly (Harrison et al. 2011). This system permitted study of how variability in the DCMD response affects the final motor output on a trial-by-trial basis (Fotowat et al. 2011).

These experiments found little evidence for an involvement of the DCMD in the initial preparatory movements leading to the jump. The DCMD firing rate threshold predicted only 36% of the variance of co-contraction onset, indicating that other neurons still play an important role at this stage. This result is not surprising since, as we saw in Section 2 escape responses can require complex calculations prior to initiation.

Nevertheless, the DCMD activity played an increasingly important role as collision became imminent. For instance, after co-contraction onset, the number of DCMD spikes precisely predicted the hind leg's motoneuron activity. The number of DCMD spikes from co-contraction onset was highly predictive of jump occurrence. Additionally, the time of DCMD peak firing rate could predict 75% of the trial-to-trial variability of the jump time from the DCMD peak firing time. In conclusion, the transformation of sensory activity into the motor program leading to visually guided jumps appears to rely on distinct attributes of a

neuron's time-varying discharge from a specific time point (co-contraction onset).

Is the DCMD the sole source of looming information to the jump motor circuitry, or are there other parallel visual pathways that could generate escapes? Ablating the DCMD altered the flexion timing but did not eliminate it, a fact that suggested that pathways beyond the DCMD must necessarily be involved (Santer et al. 2008). Locusts possess, besides the DCMD, a second pathway called the descending ipsilateral motion detector (DIMD) found in the ipsilateral nerve cord, which has near identical looming responses to those of the DCMD (Fotowat et al. 2011). In the absence of these two neurons, locusts still flex their hind legs in preparation for co-contraction; however, they rarely take off, and when they do, it is after projected collision. These results suggest that the activity of the DCMD or DIMD is likely not necessary for the initial flexion stage but plays a critical role in generating correctly timed jump takeoffs.

Conclusion

Understanding how sensory stimuli are processed by the nervous system to generate complex behaviors is a central goal of systems and computational neuroscience. In view of their biological importance, visually guided collision avoidance behaviors (VGCABs) provide a favorable model for studies of sensory coding, sensory-motor transformations, and decision-making processes, as many animals have developed specialized neural circuitry to sense and execute them. Furthermore, these behaviors must be controlled by rather simple neural circuits to generate quick and reliable avoidance responses. At the sensory level, VGCAMs usually begin as phenomenological descriptions and then focus on the study of associated neural circuits and biophysical mechanisms for implementing these computations. In this sense, an outstanding example is the case of the locust's LGMD/DCMD neurons, whose properties have been studied for over 40 years (Burrows 1996). Using experimental techniques such as electrophysiology, pharmacology, calcium

imaging, and computational modeling techniques, this work has shown that different biophysical processes work in parallel to tune the LGMD response to looming stimuli.

At the behavioral level, studies in invertebrates showed that VGCABs vary considerably depending on the animals' motor structure and living environment, ranging from ballistic-like or multistage to continually adjusted behaviors. For this reason, we need comparative studies across different species to determine the generality of the discovered mechanisms. VGCABs require computations integrating information from different sensory channels to decide whether, when, in which direction, and how intensely to perform an escape response. Therefore, it will be interesting to study how downstream circuits interpret these sensory messages in order to make an appropriate motor decision. Finally, VGCAMs can be used to frame hypotheses about circuitry, which can be directly tested by techniques such as calcium imaging and electrophysiological recordings in freely behaving animals.

Definition

The study of color vision has been aided by a whole battery of computational methods that attempt to describe the mechanisms that lead to our perception of colors in terms of the information-processing properties of the visual system. Their scope is highly interdisciplinary, linking apparently dissimilar disciplines such as mathematics, physics, computer science, neuroscience, cognitive science, and psychology. Since the sensation of color is a feature of our brains, computational approaches usually include biological features of neural systems in their descriptions, from retinal light-receptor interaction to subcortical color opponency, cortical signal decoding, and color categorization. They produce hypotheses that are usually tested by behavioral or psychophysical experiments.

Detailed Description

Although the sensation of hue is an invention of our brains, it nevertheless allows us to identify objects by one of their key physical features: their color. Our cortical neurons receive information about the world “out there” and process it in highly nonlinear ways to make sense of the environment, highlighting and grouping important items over the rest. In the case of color, this information is carried by the distribution of energy

in the photons (wavelength distribution) of the light reflected by objects. Our visual system captures these photons through a very sophisticated mechanism in our retinas, one that converts wavelength information into neural spikes and ultimately into the vivid sensation we experience. However, the result of this process bares only a small resemblance to the physical characteristics of the light originally falling on our retinas. For instance, two objects whose reflected light may differ by only a few more energetic photons may be assigned completely different color categories by our brain. The opposite may also occur: two objects reflecting remarkably different photon/energy distributions may look as having the same color to us. Our perception of color at a point in space may depend not only on the physical characteristics of the light reflected from that point but also on that of the points surrounding it. The origins of these mechanisms are deeply rooted in the lifestyles of our primate ancestors and their need to avoid predators, find suitable mates, and forage for nutritious fruits and leaves in the African forest. These tasks and a changing visual environment may have determined the properties of our color vision and its drive to collect information about the part of the environment that changes the least: the surfaces of objects. This knowledge may help categorize the objects (edible? dangerous?) and therefore improve our chances of survival. In view of this, it is easy to understand why our brain has evolved its nonlinearities to favor a representation of the world that enhances and improves on the mere physics of the visual environment.

The very properties that aid survival also make the problem of predicting color sensation from the wavelength patterns of light stimulating our retinas very complex and mathematically difficult to address. Color vision scientists have made a great deal of advance, making sense of what is in essence a complex nonlinear problem. Each subdiscipline studies the phenomenon from its own unique perspective, with computational approaches contributing to our understanding at every level, from neurophysiology to behavior.

The Retina

The retina is perhaps the best known part of our visual system. It contains three types of photoreceptors or cones that are selectively stimulated by photons according to their energy (wavelength). These receptors (named *L*, *M*, and *S* because of their preferences for long, medium, and short wavelengths, respectively) are light-sensitive neurons which fire electrical impulses when exposed to light of wavelengths near their preferred value. Their sensitivity has been quantified (Stockman and Sharpe 2000) in the form of three spectral sensitivity functions (see Fig. 1). Notice that since each of the cones could be stimulated by

photons with energies within a wide range, long-wavelength-preferring cones could be stimulated by medium-wavelength light. Given that cones also respond to light intensity, intense light of suboptimal wavelength can produce the same firing rate as low-intensity light of optimal wavelength. This is the reason why many (in fact infinite) wavelength distributions can produce similar outputs from the cones. Two lights of different wavelength distributions that produce the same retinal output are called *metamers*.

Receptor and post-receptor mechanisms were anticipated in the nineteenth century (well before any physiological observation) in the form of a trichromatic theory by Young (1802) and

Color Vision, Computational Methods for, Fig. 1 Schematics of the chromatic signal processing in the retina. The figure on the *left* shows the three human photoreceptors and how they connect to form the three post-receptoral mechanisms by addition and subtraction. Chromatic information is obtained by sampling the spectrum around different wavelengths and comparing the

output of at least two different types of photosensitive neurons. Two of the post-receptoral mechanisms are chromatically opponent and one ($L + M$) is achromatic. Panels on the *right* show the spectral sensitivity of each chromatic mechanism. The terms $L + M$, $L - M$, etc. refer to the sign of the operation and do not represent the weight of each mechanism in the sum

Helmholtz (1867) and a color opponent theory by Hering (1875). The first postulates that color vision is based on three fundamental mechanisms as illustrated at the top of Fig. 1, and the second postulates that color vision arises from the workings of three opposed mechanisms: red green, blue yellow, and light dark (see bottom of Fig. 1). Each theory was an attempt to explain different phenomena such as how mixtures of colored light create a different color or the observation that some opposing pairs of sensations cannot be simultaneously experienced (e.g., there is no reddish-green color) and afterimages (illusory colors that appear after our retinas have been overexposed to colored stimuli) (Gregory 1998). Our current knowledge of the interaction between cone photoreceptors and light can be expressed mathematically as the integral of the product between the electromagnetic power distribution of the light and each of the cones' spectral sensitivity functions (L , M , and S curves shown in Fig. 1):

$$\varepsilon_i = \int_{\lambda} S_i(\lambda)P(\lambda)d\lambda \quad (1)$$

In Eq. 1, ε_i represents the excitations of the three classes of cones ($i = L, M, S$), $S_i(\lambda)$ is their corresponding spectral sensitivity, and $P(\lambda)$ is the spectral power distribution of the light falling on them. Since in real life light measurements are only available at a series of finite wavelengths, the integral in Eq. 1 is generally approximated to a finite sum over the visible spectrum (400–700 nm).

Computational Methods for the Retina

In practice, it is unlikely that we know the full spectrum of the light falling on the retina. It is more common to operate retinal models based on images obtained by commercial cameras. These are also modeled by Eq. 1, but their sensor sensitivities are usually unknown. Some devices are capable of producing images in standard, device-independent color spaces such as the CIE1931 XYZ system or the sRGB color standard, which are easily convertible following a simple set of

formulae (Poynton 2003; Green and MacDonald 2002). Once we know the XYZ coordinates, we can obtain the chromaticity coordinates x, y using the following:

$$\begin{aligned} x &= \frac{X}{X+Y+Z} \\ y &= \frac{Y}{X+Y+Z} \end{aligned} \quad (2)$$

From there, it is possible to obtain the cone excitations using Y (luminance) and the following transformation (Wyszecki and Stiles 1982a):

$$\begin{aligned} \varepsilon_L &= Y[0.15514x/y + 0.54312 - 0.03286(1-x-y)/y] \\ \varepsilon_M &= Y[-0.15514x/y + 0.45684 - 0.03286(1-x-y)/y] \\ \varepsilon_S &= Y[0.00801(1-x-y)/y] \end{aligned} \quad (3)$$

In the case of Eq. 3, ε_i values correspond to the Smith and Pokorny cone fundamentals (Smith and Pokorny 1975) and the chromaticities ought to be derived from the Judd-modified CIE1931 standard color matching functions (Judd 1951). The plot at the top of Fig. 1 shows an example of cone fundamentals, with the sensitivity of each cone plotted as a function of wavelength. Color matching functions are obtained from psychophysical experiments where subjects have to visually match the sensation produced by spectrally narrowband stimuli to a mixture of three spectrally broadband lights. It is possible to mathematically obtain cone fundamentals from such experiments, given certain assumptions (Wyszecki and Stiles 1982b). Although Smith and Pokorny did not specify the coefficient necessary to obtain ε_s , the value of 0.00801 was chosen to take into account the relative strengths of the two post-receptor neural opponent mechanisms (see below).

Equation 3 provides a good approximation for transforming the output of cameras and monitors once we can express it in the CIE1931 XYZ system. However, in most cases this is not possible, and devices such as cameras and monitors need to be characterized to convert their outputs to cone excitations. There are several methods for characterizing cameras which include gamut mapping between a known target and the camera

output (Cheung et al. 2004; Parraga et al. 2010), estimation of the camera's sensor sensitivities (Westland and Ripamonti 2004; Barnard and Funt 2002), and mixtures (Parraga et al. 2010). They transform the output of a commercial digital camera into a device-independent color space such as the CIE1931 XYZ.

Receptoral Gain Control Mechanisms

In the retina, there is a nonlinear relationship between the input and the output of the cone photoreceptors, which is often characterized as a gain control mechanism (output signals are modified by signals from the same or different cones). This mechanism converts cone excitations into a contrast representation such as

$$C_i = \frac{\Delta \varepsilon_i}{\varepsilon_i^b - \varepsilon_i^0}; \text{emi} = L, M, S \quad (4)$$

where ε_i^b represents the cone excitation produced by the background (the adaptation state), ε_i^0 is a constant, and $\Delta \varepsilon_i$ represents the excitation difference between the cone considered and the background (Stockman and Brainard 2010). The i subindex discriminates between the three types of photoreceptors.

One of the reasons for this normalization is to reduce the massive intensity range present in the visual environment (in a typical sunny day, variations in intensity between shaded and illuminated objects can reach 9 orders of magnitude), which cannot be encoded directly by the output of single neurons (e.g., retinal neurons can encode ranges of approx. 50–1) (De Valois 2004).

Post-Receptoral Color Processing

The signals transmitted by cones are combined and encoded in a series of steps by neurons in the retina (the last processing layer is formed by neurons called ganglion cells) and transmitted to an area inside the thalamus called the lateral geniculate nucleus (LGN). The majority of these signals (80% of the fibers reaching the LGN)

passes through a layer of ganglion cells called *parvocellular* (or parvo) cells (De Valois 2004). At this stage, the information is organized both spatially and chromatically in opponent signals. For example, a parvo cell in the central retina may receive input from a single L or M cone and weight it against input from a small group of surrounding cones (see Fig. 2).

Each ganglion cell is stimulated by light falling on a physical part of the retina that contains the cones to which it is connected (its receptive field). As a result of the wiring shown in Fig. 2, parvo cells output a signal that is spatially and chromatically opponent and conveys both intensity (i.e., brightness) and wavelength information (i.e., color) from the light falling on its receptive field. Thus parvo cells perform a “double duty,” carrying information about both intensity and color. The right part of Fig. 2 shows how intensity changes in light increase the cell's antagonism, conveying information about the smallest possible unit (a cone), while chromatic changes produce a synergistic response in the center and surround, thus increasing the number of cones contributing to the signal. For this reason, parvo cells in Fig. 2 convey finer detail information (higher spatial frequencies) about intensity than for color. In other words, when light varies spatially in color, the same cells can only carry information about its coarse spatial distribution (lower spatial frequencies). This imbalance has been confirmed psychophysically by our greater ability to detect fine patterns of achromatic light and coarse patterns of colored light (De Valois and De Valois 1988) and matches the information content of natural scenes (Parraga et al. 2002). This combination of spatial and chromatic opponency in parvo cells appears to be a sophisticated mechanism to optimally extract information from the visual environment, carrying both chromatic and achromatic signals over different spatial frequency bands (multiplexing).

Computationally, it is common to model the center-surround receptive field structure by convolving the color opponent representations with Gaussian kernels of opposite sign and different standard deviations (difference of Gaussians). For example, one kernel is applied to the L-cone

Color Vision, Computational Methods for, Fig. 2 Schematics of the spatiochromatic opponent processing in the retina. Parvocellular ganglion cells collect input from a single cone and compare it with a pool of surrounding cones. In the case of $L - M$ opponency, this leads to four possible combinations, as illustrated in the figure. The *right* part of the figure shows an example of

how the same cell can carry information about both intensity and color. If the light falling on the cell's receptive field changes its intensity, both center and surround are stimulated, therefore increasing their antagonism. If the same light changes its color toward *red*, the center is stimulated and the surround is depressed, contributing less to reduce the ganglion cell output signal (therefore the + sign)

representation and another (of greater standard deviation) to the M-cone representation and the results are subtracted from each other. This process is equivalent to subtracting a blurred version of the M-cone-excitation image (the surround) from another slightly blurred version of the L-cone excitation (the center). A similar algorithm can be applied to obtain $S - (L + M)$ opponency. Similarly to parvo, there exist in the retina two other types of ganglion cells. The *koniocellular* (or konio) cells that carry information about S-cone excitation relative to their surrounds ($S - (L + M)$ and $-S + (L + M)$) and the *magnocellular* (or magno) cells that receive excitatory output from all three types of cones, therefore, are insensitive to color (De Valois 2004). Figure 1 illustrates this opponency from a spectral point of view.

The three types of ganglion cells described above connect to specialized layers of neurons in the LGN. The presence of these LGN cells representing different aspects of the light captured

by cones has inspired the creation of color spaces based on the properties of these neurons. The best known is the MacLeod–Boynton cone-excitation space (MacLeod and Boynton 1979) which is based on the coefficients of Eq. 3 plus an arbitrary condition that the relationships among the sensitivities of the three receptor mechanisms at 400 nm (see Fig. 1) will be given by Eq. 5:

$$S_L(400) + S_M(400).36em = .36emS_S(400) \quad (5)$$

where $S_i(400)$ is the sensitivity of each cone photoreceptor at 400 nm. To obtain the coordinates of the MacLeod–Boynton receptor space, it is necessary to convert the L -, M -, and S -cone excitations to coordinates l -, m -, and s -, respectively, using the following transformation:

$$l = \frac{L}{L + M}; emm = \frac{M}{L + M}; ems = \frac{S}{L + M} \quad (6)$$

The normalization provided by Eq. 5 constrains the value of s in Eq. 6 between 0 and 1.

An extension of cone-excitation spaces are cone-contrast spaces, which address the issues posed by the receptor gain control mechanisms described in Eq. 4. Two popular cone-contrast spaces were created by Derrington et al. (1984) and Boynton (1986) following different assumptions about the neutral points (crossings of the $L - M$ and $S - (L + M)$ functions of Fig. 1). Cone-contrast representations take into account the cone excitation produced by the background and rescale the signal accordingly. The new coordinates become

$$C_i = \frac{\Delta \varepsilon_i}{\varepsilon_i^b}; \text{emi} = L, M, S \quad (7)$$

where $\Delta \varepsilon_i$ is the cone-excitation difference between the signal and a given reference level (the background). ε_i^b is the cone excitation produced by the background. In this new representation, the background excitation becomes the origin of the new system. Cone-contrast spaces provide a representation of the input signal arriving at later stages in the visual pathway.

Cortical Color Processing

LGN neurons project to the primary visual cortex in the occipital part of the brain (also known as striate cortex or area V1). From there, visual information is sent to the so-called extrastriate visual cortical areas (named V2, V3, V4, and V5). Each part of the retina is mapped into V1 with a very precise correspondence between the

visual field and its related location in the primary visual cortex. A large portion of V1 is dedicated to the center of the retina, where the abundance of cones is highest and the receptive field smallest. In contrast to the well-defined, opponent-color information-carrying neurons found in the retina and LGN, color-sensitive cortical neurons respond to many other properties of the visual stimulus such as contrast, object orientation, shape, etc. This is thought to be the reason behind many illusory phenomena where the color of the area we gaze is influenced by patterns of the surrounding area (chromatic induction, see Fig. 3) and color constancy (Brainard 2004).

Originally, color processing in the visual cortex was thought to be modular and separated from other forms of perception. This view was supported by studies in cerebral achromatopsia (a lesion in the brain that causes loss of the ability to recognize colors without loss of form and motion perception) and others (Zeki 1993). Today's prevalent view is that V1 is strongly stimulated by color, with about 50% of its neurons responsive to some kind of chromatic stimulus, with $L - M$ being the preferred direction (Shapley and Hawken 2011). Areas V2 and V4 also respond to color; however, many of their neurons respond equally to achromatic patterns. Two intriguing classes of color-processing neurons were found in the primary visual cortex: single- and double-opponent cells (Shapley and Hawken 2011; Hurlbert 2003; see Fig. 4). The former respond best to large areas of color, while the latter have preference for color boundaries,

Color Vision, Computational Methods for, Fig. 3

The figure shows the influence of surrounding patterns on the perceived color of a central area. In both figures, the inverted “U” bar has the same RGB values, but it is perceived differently according to its surroundings. This phenomenon is called “chromatic induction”

Color Vision, Computational Methods for, Fig. 4 Cartoon examples of single-opponent and double-opponent color-processing cells. Single-opponent cells are insensitive to edges and do not prefer any oriented stimuli. They respond strongly to colored patches. On the other hand, double-opponent cells are strongly selective for chromatic edges and have a preferred orientation

patterns, and textures. Both types of neurons have been linked to the perceptual phenomena shown in Fig. 3.

There have been reports in the literature about a spatial segregation of color-selective neurons in V1 and V2. A number of optical imaging electrophysiological and microelectrode studies have found the presence of clusters of color-selective neurons, although there are still negative results and the issue has not been definitively resolved (Shapley and Hawken 2011).

Computational Models of Color Processing in the Visual Cortex

Computational models of cortical processing can be categorized as either primarily

phenomenological, i.e., trying to capture the observed phenomena in a convenient mathematical form, or mechanistic, i.e., trying to show how observed phenomena arise from biologically grounded neural mechanisms. A typical color vision model contains a preprocessing stage where the input image is converted to an L -, M -, or S -cone-excitation representation, a cone opponency stage that weights the output of cones to produce opponent signals, and other post-receptoral stages which may include normalizations by neighboring units and weighting parameters. The center-surround receptive field interaction is usually modeled via a pyramid of 2-dimensional Gaussian or Gabor operators that convolve the image to obtain chromatic and achromatic information at different spatial scales and orientations. A final layer can also be implemented to account for single- and double-opponent cell processing.

Chromatic induction demonstrations like those shown in Fig. 3 have inspired some computational attempts to model color processing in the visual cortex, trying to predict the effects of surround stimuli on the perceived color of a central patch. Examples of these are the models of Singer and D’Zmura (1995) and Spitzer and Barkan (2005) and Otazu et al.’s CIWaM (2010). The latter consists of a cone-receptor stage that separates the input into two chromatic and one achromatic channels: a wavelet pyramid to model spatiochromatic processing in the cortex, including normalization effects by neighboring neurons (divisive normalization) (Heeger 1992), and a weighting function to mimic the spatial filtering of the human visual system. A later version of CIWaM was capable of predicting unconstrained eye movements in human subjects (Murray et al. 2011).

A family of computational approaches to color processing takes advantage of the tools currently available in computer science for tasks such as object recognition. For example, one approach consists of applying shape-based descriptors such as scale-invariant feature transform (SIFT) on the post-receptoral color representations. SIFT will learn “interesting features” of an object in a set of training images which can

be later used to identify the object in the dataset. Other approaches involve a set of shape-based descriptors computed from gray-scale pixel intensities, which are in turn concatenated with hue histograms. An improvement has been proposed by Van de Weijer and Schmid who concatenated a hue histogram with gray-scale SIFT image descriptors (Gevers 2012), while Zhang et al. (2012) described a hierarchical model of color processing inspired in the primate visual cortex. They produced chromatically opponent channels using operators that resemble single- and double-opponent cells and outperformed the object recognition of previous approaches.

Color Constancy

The human visual system has the ability to perceive objects as having a well-defined color despite the fact that they reflect light according to their own pigmentation, geometry, and the wavelength content of the illumination. During a typical day, natural daylight changes its color quite dramatically, but we are mostly unaware of its full effect on the surfaces of objects. As we have seen before, the distribution of power as a function of wavelength in the light reaching our retinas determines how we perceive color. In the case of light reflected from objects, this power distribution depends on several factors. Equation 8 provides a simplified description of the problem (Brainard 2004):

$$C(\lambda) = E(\lambda)R(\lambda) \quad (8)$$

Here $C(\lambda)$ is the spectral power distribution of the light reaching our retina, $E(\lambda)$ is the spectral power distribution of the illumination, and $R(\lambda)$ is the spectral reflectance of the surface. Equation 8 assumes that the illumination is spatially uniform and surfaces are Lambertian (diffusely reflective, with no specularities). Of these factors, only $R(\lambda)$ is intrinsic to the objects, while $E(\lambda)$ changes according to the type of illumination, physical location, time of the day, etc. In summary, to produce a stable scene in

terms of color, the human visual system disentangles the two factors at the right side of Eq. 8. This is a mathematically ill-posed problem, given that there are infinite possible combinations of illumination and reflectance that produce the same reflected light. To solve it, the human visual system may resort to information from previous experience, scene features such as specular reflections and interreflections, memory of colors, etc.

The problem of illumination removal is ubiquitous. For example, in computer vision, there are applications that require illumination stability in order for algorithms to work. In photography, users expect the image to represent the scene “as they saw it,” not the actual physical values. Many popular computational approaches try to solve this problem by taking into account the information intrinsic to the image, rather than the physiological or anatomical mechanisms of the visual system. For practical reasons, methods were developed to return an image that approximately represents the intrinsic color of objects, discounting the effects of the illumination (canonical image). This image can be then “reilluminated” to create conditions close to the observer’s perception. Illuminant removal methods contain different statistical hypothesis, the most popular being the “gray world” assumption, which states that the *average reflectance of a scene is achromatic*. Another popular hypothesis (called “MAX-RGB”) takes advantage of some properties of white surfaces and specular reflections and is based on the assumption that *the maximum reflectance of a scene is achromatic*. Once a hypothesis is introduced, the computational algorithm returns an image that meets the hypothesis. Many of these solutions are strongly dependent on whether the input image complies with the hypothesis and are prone to fail in particular cases. For example, a “gray world” algorithm may fail when the average color of the scene is not gray. The main drawback of this family of computational approaches is that they do not provide much insight about the mechanisms that are behind color constancy. See Gevers (2012) for a comparison of illuminant removal methods.

Color Appearance

The models and the physiologically based color spaces described above have been created to handle the perception of colors viewed in isolation and in controlled, fully adapted conditions. However, the perceptual appearance of colors in naturalistic viewing conditions depends on so many external factors (surround, background, illuminant, etc.) that a series of sophisticated models have been created to account for them. These so-called color appearance models are not constrained by attempts to incorporate elements of the physiology (Fairchild 1998).

Comparative Analysis of Half-Center Central Pattern Generators (CPGs)

Jonathan E. Rubin
Department of Mathematics, University of Pittsburgh, Pittsburgh, PA, USA

Definition

CPGs are networks of neurons that can produce rhythmic activity, featuring a stereotyped sequence of phases that repeats in a periodic-like manner, without receiving rhythmic inputs from an outside source. Half-center CPGs, also known as half-center oscillators, are CPGs consisting of two components connected by reciprocal synaptic inhibition. While the coupled network exhibits a two-phase pattern, with one component exhibiting a high activity level and the other at a low activity level in each phase, the individual components are not able to switch between sustained high and low activity phases in isolation. Comparative analysis of half-center CPGs is the study of how specific features of half-center CPGs translate into particular properties.

Detailed Description

A half-center CPG consists of a pair of components and the coupling between them. Each component may be an individual neuron or a population of neurons. In a half-center oscillation, each component switches back and forth between sustained low activity and high activity states. The level of activity in a neuron is related to its membrane potential. Transmembrane currents allow ions to pass through channels into or out of a neuron, altering its membrane potential or voltage. These channels may be blocked by two types of gating processes, and changes in the extent of blockage are called (de)activation or (de)inactivation, depending on the gating type. Many of these ion currents are intrinsic to a neuron, meaning that the extent to which they flow is determined by the neuron's own voltage and the ion concentrations in the extracellular medium surrounding the neuron, independent of the activity of other neurons nearby. Other currents are synaptic and are induced by the activity of other neurons. When active, neurons release neurotransmitters that activate synaptic currents in other neurons, their postsynaptic targets. In half-center CPGs, these synaptic currents are inhibitory. If the voltage of a postsynaptic neuron is at a typical physiological level, then such a current lowers its voltage, making it harder for the postsynaptic neuron to activate in the short term. Thus, the primary features of a half-center CPG consist of the sets of ion currents intrinsic to its components; the time scales, voltage dependences, strengths, and other characteristics of these currents; the pattern of synaptic connections between its components; and the characteristics of the synaptic currents that these connections induce. To compare properties of different half-center CPGs efficiently, however, it is useful to group together various half-center CPGs with common emergent features that lead to similar properties.

Classifying Half-Center CPGs: Low and High Activity States and Transitions Between Them

For simplicity, it is convenient to refer to components of CPGs as individual neurons, although the

following discussion can be generalized to cases where the components are neuronal populations. The activity level of a neuron can be quantified using its membrane potential or its rate of generating spikes, which are brief pulses of elevated potential also known as action potentials. Usually high potentials are associated with high rates of spike generation, although there are circumstances in which this link does not hold. An isolated neuron can be in a low activity state, in a high activity state, or in a regime where it spends a significant time in each state with rapid transitions between states. By definition, the neuronal components of a half-center CPG cannot be in the latter state in isolation, as can be checked experimentally by preventing the induction of synaptic currents, although they must enter this rhythmic state once they are coupled synaptically (Hooper 2001). For an isolated neuron to maintain a low activity state, there must be a low voltage at which its intrinsic ion currents are balanced. A high activity state may correspond to the balancing of a neuron's intrinsic currents at a high voltage or to sustained spike generation, without extended pauses between spikes. If we represent a neuron by a system of ordinary differential equations encoding the relations between membrane potential and ion current flows, ignoring spatial effects and stochasticity, then states of balanced current are equilibrium points of the system, while a state of sustained spiking is a periodic solution. If a biological neuron or mathematical model neuron tends to one of these states over time from an appropriate set of starting conditions, then the attained state is an attractor for the system.

These ideas lead to a classification of half-center CPGs in terms of which attractors are present in the absence of inputs, assuming these are unique. Theoretically, the possibilities are:

- L-L: both neurons have attracting equilibrium points in low activity states in the absence of inputs
- L-H: one neuron has an attracting equilibrium point at a low activity state, and one has an attracting high activity equilibrium point or oscillation in the absence of inputs
- H-H: both neurons have attracting high activity states, either equilibrium points or oscillations, in the absence of inputs

In each case, when the neurons are coupled with inhibition, both must transition repetitively between low and high states, taking turns being active, for a CPG rhythm to result. Thus, it is important to check that this alternation is possible in each of the cases in this classification. To keep things relatively simple, it is helpful to assume that the synaptic inputs from a neuron turn on quickly when that neuron's activity level becomes sufficiently high and turn off quickly when its activity level is sufficiently low, although theoretical work has considered slower input changes as well. It turns out that there are certain types of transitions between states that can occur in each case and that the most useful classification is in terms of these transition mechanisms, taking into account both intrinsic and synaptic properties of a model, rather than in terms of the intrinsic attractors of model units alone.

A transition-based classification of half-center CPG models uses the categories of *intrinsic escape*, *intrinsic release*, *synaptic escape*, and *synaptic release* (see Wang and Rinzel 1992; Skinner et al. 1994), defined in terms of which neuron and which processes associated with that neuron control the transitions between activity states. To set up and understand this classification, it is useful to note that certain processes associated with voltage changes are relatively fast while others are relatively slow. The former group includes changes in activation or inactivation of certain currents in response to changes in voltage as well as changes of voltage itself in response to changes in availability of currents, while the latter includes changes in other (in)activation levels as well as changes in concentrations of certain ions within a neuron.

- In *intrinsic escape*, the slow processes of the neuron in a low activity state allow it to make a transition to a high activity state. In doing so, its inhibition to the other neuron turns on, causing the other neuron to make a high-to-low transition

- In *intrinsic release*, slow processes of the neuron in a high activity state cause it to make a transition to a low activity state. In doing so, its inhibition to the other neuron turns off, causing the other neuron to make a low-to-high transition
- In *synaptic escape*, the threshold for activation of synaptic inputs is low. The neuron in a low activity state undergoes small increases in voltage due to its slow processes. Due to the low synaptic activation threshold, this voltage increase is enough to introduce some inhibition of the high activity neuron. This inhibition suffices to induce a high-to-low transition in the high activity neuron, and the resultant loss of inhibition of the low activity neuron causes it to switch to a high activity state
- In *synaptic release*, the threshold for activation of synaptic inputs is high. The neuron in a high activity state undergoes small decreases in voltage due to its slow processes. Due to the high synaptic activation threshold, this voltage decrease is enough to relieve some inhibition of the low activity neuron. This loss of inhibition suffices to induce a low-to-high transition in the low activity neuron, and the resultant inhibition of the high activity neuron causes it to drop to a low activity state

This classification is simplest if it is assumed that the two neurons in the half-center CPG model are identical. More generally, it makes sense under the assumption that both transitions in the network are of the same type. A generalization of the classification would allow for two different transition types within one network oscillation; one neuron might activate through intrinsic escape, for example, while the other neuron might activate through intrinsic release. Another observation is that none of these transition types explicitly specifies a particular timing between the transition of one neuron and the corresponding transition of the other neuron. For example, one neuron might undergo a high-to-low transition intrinsically, releasing the other neuron from inhibition. This change might be enough to induce an immediate low-to-high

transition in the released neuron. On the other hand, additional time might be needed before the released neuron could activate.

Finally, note that this classification is related to the classification based on single neuron attractors. This relation can be illustrated using examples involving particular currents.

Example 1 – L-L/intrinsic release with I_T . Suppose that both neurons have attractors at low activity states without inputs and have T-type calcium currents, I_T , which are inactivated at these attracting states. If one neuron is placed in a high activity state and the other in a low activity state, the low activity neuron is inhibited, and its voltage is reduced. I_T is a positive inward current that slowly deinactivates at low voltages. Thus, if the high state neuron transitions to a low state, the rapid release from inhibition combined with the enhanced availability of I_T can allow the formerly inhibited neuron to activate, inhibiting its partner, in a process called *post-inhibitory rebound*. The whole cascade can repeat periodically and sustain a half-center oscillation.

Example 2 – H-H/synaptic release with I_{K-Ca} . Suppose that both neurons have attracting high activity states without inputs and have a calcium-dependent outward potassium current, I_{K-Ca} , which is activated at these attracting states. If one neuron is put into a low activity state in the absence of inputs, it will transition to high activity on its own, but suppose that the other neuron has just been allowed to become active and supplies sufficient inhibition to block this transition. Over time, the active neuron's I_{K-Ca} activates, and this outward current reduces its voltage. If this voltage reduction is sufficient, it may reduce the inhibition level to the other neuron. As a result, the other neuron may become active and inhibit its partner, causing a high-to-low transition in the formerly active neuron.

Example 3 – H-H/intrinsic escape with I_{K-Ca} . In the above scenario, it is also possible that the neuron in the low activity state can escape without any reduction of inhibition, because its I_{K-Ca} deactivates over time. Depending on

model parameters, this effect may be enough to allow it to transition to the high state and suppress the formerly active neuron.

Several subtle yet important points arise from this type of analysis: (1) Different transition mechanisms can arise even from the same intrinsic neuron features, depending on the quantitative details. Once neurons are coupled into a network, their individual properties can become masked or overshadowed by network interactions (Ausborn et al. 2018; Rubin and Smith 2019). (2) Certain combinations of intrinsic neuron features and transition mechanisms are possible, while others are not. That is, neurons' intrinsic dynamic properties can constrain which types of network dynamics can emerge (Ausborn et al. 2018). (3) The same transition mechanism can result despite the involvement of different neuron features. In particular, distinct current types can be associated with the same transition mechanism; for example, the depolarization-activated outward current I_{K-Ca} or the depolarization-inactivated inward current I_T can be replaced by the depolarization-inactivated inward current I_{NaP} in the above examples, as long as model parameters are tuned appropriately (Fig. 1, left; cf. Izhikevich 2007).

Transition-Dependent Properties of Half-Center CPGs

A classification of half-center CPGs in terms of transition mechanisms is useful because various properties are determined, or predicted to be determined, by which transition mechanism is present. Consider a theoretical half-center CPG composed of two identical neurons with low activity attractors and with transitions by intrinsic release. Suppose that an equal excitatory current, which raises voltage, is applied to both neurons. Whichever neuron is active controls the next phase transition in the coupled network, and therefore the effect of this current will be determined by its impact on the neurons when they are active, as long as the current is not so large that it changes the transition mechanism (Skinner et al. 1993; Curtu et al. 2008). Since the current is excitatory, it will delay the high-to-low transition of each active neuron, prolonging the period of the CPG oscillation (Fig. 1, right bottom). Alternatively, suppose that the neurons in the CPG have high activity attractors and that the CPG rhythm involves transitions by intrinsic escape. In this case, whichever neuron is suppressed controls the next phase transition in the coupled network. If an excitatory current is applied equally to

Comparative Analysis of Half-Center Central Pattern Generators (CPGs), Fig. 1 Half-center oscillations with transitions by escape and release. (Left) A two-neuron model with reciprocal inhibition and persistent sodium current generates half-center oscillations using escape (top row) or release (bottom row). (Right) Number of

completed oscillations in a 1 s simulation with applied current I_{app} when transitions are by escape (top row) or release (bottom row). For example, five oscillations mean that one cell oscillated three times and the other two times during the simulation

both neurons, this current will raise their voltages and thus accelerate the escape of the suppressed neuron. This effect shortens the period of the CPG oscillation (Fig. 1, right top). In a half-center CPG with a moderate synaptic threshold such that transitions remain intrinsic, a switch from intrinsic release to intrinsic escape may be achieved by applying progressively stronger excitatory current, shifting the neurons' attractors from low activity to high activity states; this switch may be abrupt or may be interrupted by a current range lacking oscillations, in which release is blocked but escape is not yet possible. In either case, the dependence of CPG period on applied current level is non-monotonic.

A more complicated situation is the application of unequal excitatory current levels to the two neurons in a half-center CPG (Daun et al. 2009; Ausborn et al. 2018). This scenario is likely functionally relevant, as modulatory inputs to CPGs may target distinct components differently. In a CPG with transitions by intrinsic escape, the neuron receiving a stronger current will escape faster, but, under fairly general conditions, the network equilibrates such that the duration of the other neuron's suppressed phase remains approximately constant. In contrast, if transitions occur through intrinsic release, then current availabilities tend to equilibrate such that little change in either oscillation phase duration results. If transitions occur through synaptic release, then the low-to-high transition of the neuron with greater stimulation is accelerated, but that of the other neuron is delayed, such that both phase durations are altered. Thus, of these possibilities, only intrinsic escape allows for independent modulation of the durations of the two activity phases in a half-center oscillation (Daun et al. 2009), as would appear to be desirable to maximize the flexibility of behaviors driven by CPG rhythms and is observed in data on fictive locomotion and simulations that reproduce it (Yakovenko et al. 2005; Rybak et al. 2006).

A third scenario that can yield different response properties of half-center CPGs is the application of transient stimulation. Suppose

that a CPG is oscillating with a period T . Assign time 0 to correspond to the time when the voltage of one cell increases through some fixed level. Under this time labeling, the time at which this same event next occurs is time T . For each $t \in [0, T]$, define a phase $\phi = t/T \in [0, 1]$. A phase response curve (PRC) can be defined by plotting the advance or delay in phase introduced by a transient current injection as a function of the oscillation phase at which the injection occurs (Ermentrout and Terman 2010). The PRCs that result when the transitions within an oscillation are due to escape are quite different from the PRCs for release-based transitions (Fig. 2; Zhang and Lewis 2013). For example, label the voltages of neurons in a half-center CPG as v_1, v_2 . Suppose that $\phi = 0$ occurs when the voltage v_1 reaches its maximum. If the two neurons are identical, then v_2 reaches its maximum at $\phi = 1/2$. If transitions occur by escape, then stimulation of neuron 1 at $\phi \in (0, 1/2)$ will have little impact, since the next phase transition relies on the escape of unstimulated neuron 2. Stimulation at $\phi \in (1/2, 1)$, when neuron 1 is suppressed, may accelerate its escape and hence advance the phase of the oscillation, although details relating to the timing, amplitude, and duration of stimulation matter. If transitions occur instead by release, then stimulation of neuron 1 at ϕ in some range within $(0, 1/2)$ will help it continue to suppress neuron 2 and hence cause a delay, especially if v_1 is dropping toward synaptic threshold when the stimulation arrives. Stimulation at $\phi \in (1/2, 1)$ in this case arrives when neuron 1 is suppressed and has little effect on when neuron 2 releases neuron 1 and hence relatively little impact on phase. In summary, the advance or delay in oscillations induced by a transient stimulation at a known oscillation phase depends on whether the transitions in a network are by escape or release. A major phase delay can only arise in the release case, and stimulation in the later part of the active phase of the neuron being stimulated is particularly well suited to distinguish escape (little change in phase) from release (significant phase delay) (Zhang and Lewis 2013).

Comparative Analysis of Half-Center Central Pattern Generators (CPGs), Fig. 2 PRCs for half-center oscillations depend on whether transitions occur by release (left) or escape (right). Top curves (solid blue or dashed green) show Z_1/T , a measure of phase advance or delay, as a

function of the phase at which stimulation is applied to the neuron with a voltage trace of the corresponding type shown in the *bottom* panels. (Figure reproduced from Zhang and Lewis (2013) with permission of Springer-Verlag)

Compartmental Models of Spinal Motoneurons

Randy Powers
Department of Physiology and Biophysics,
University of Washington, Seattle, WA, USA

Definition

Compartmental neuron models represent the complex geometry of a neuron as a set of electrically connected compartments, each of which is considered to be isopotential (i.e., the membrane voltage does not vary along the length of the compartment). Compartmental models of spinal motoneurons can be divided into three groups based on the extent to which they rely on a simplified version of dendritic morphology: (1) detailed compartmental models, which attempt to accurately represent the dendritic morphology based on anatomical reconstructions of stained motoneurons; (2) cable models, in which the branching structure of the dendritic tree is collapsed into one or more equivalent cables; and (3) two-compartment models, in which the dendritic tree is represented by a single lumped compartment that is connected to a compartment representing the soma and initial portion of the axon.

Detailed Description

Motoneurons have the largest dendritic trees of any neuron in the mammalian central nervous system (Kernell 2006). Unlike pyramidal and Purkinje neurons, whose dendritic trees primarily project in a single plane, motoneuron dendrites typically project radially from the soma in all directions and branch extensively. As a result, it is extremely difficult to record directly from motoneuron dendrites, and our understanding of the properties of motoneuron dendrites is based almost exclusively on indirect evidence. Compartmental models of motoneurons are therefore useful tools to infer dendritic properties based on intracellular and whole-cell recordings from the soma.

Equivalent Cylinder Representation of the Dendritic Tree

Early compartmental models of motoneurons represented the dendritic tree as an equivalent cylinder. Wilfrid Rall showed that if dendritic branching followed certain rules, the entire dendritic tree could be collapsed into a single equivalent constant diameter cylinder. This allowed the use of linear cable theory to derive analytical solutions for the effects of injecting current at one point on the cable on the current and voltage measured at other points along the cable (Jack et al. 1975; Koch 1999; Rall 1977; Rall et al. 1992). This theory provided estimates of the electrical length of the dendrites based on measurements of the decay of somatic membrane voltage following a brief pulse of injected current. The distal ends of motoneuron dendrites were estimated to be an average of 1–2 length constants (λ) away from the soma. (A length constant is distance over which the voltage produced by a steady-state injection of current applied at one point on the cable falls to 1/e of its value at the point of current injection.) These estimates implied that distal synapses could exert an appreciable effect on the somatic membrane potential, contrary to earlier suggestions (Eccles 1964). The

theory also was used to estimate the relative location of synapses based on the size and time course of synaptic potentials measured at the soma.

Formulation of Compartmental Models

Although the equivalent cylinder approximation and linear cable theory were extremely useful in providing information about the basic electrical properties of motoneurons as well as the flow of synaptic current in the absence of voltage-dependent conductances, the compartmental representation is needed to model current and voltage changes along the cable in the presence of voltage-dependent conductances. In the compartmental representation, the cable (or branched dendritic tree) is divided into discrete compartments, each of which is assumed to be isopotential along its length. This representation replaces the cable equation, which is partial differential equation that is first order in time and second order in space, with a set of coupled, ordinary first-order differential equations describing current flow in each compartment and between adjacent compartments.

The basic equation describing current flow in a compartment is based on Kirchhoff's current law, which states that for each compartment the net current through the membrane (i_m) is equal to the net longitudinal current that enters and leaves the compartment through the interior of the compartment. The membrane current is in turn composed of capacitative current and ionic current. The membrane equation for compartment j , connected to compartments $j - 1$ and $j + 1$, is thus

$$c_{m_j} dV_j/dt + I_{ion_j} = g_{j-1,j}(V_{j-1} - V_j) - g_{j,j+1}(V_j - V_{j+1}),$$

where V_{j-1} , V_j , and V_{j+1} are the membrane potentials across compartments $j-1$, j , and $j+1$; c_{m_j} is the capacitance of compartment j ; and $g_{j-1,j}$ and $g_{j,j+1}$ are the coupling conductances (reciprocal of the axial resistances) between adjacent compartments (Segev et al. 1989). If we divide the ionic current into that following across a voltage-independent leak conductance (g_L) and that flowing across a number of different voltage-dependent conductances ($\Sigma g_i(V)$) and rearrange terms, the basic differential equation is

$$dV_j/dt = (1/c_{m_j}) \left(-g_L(V_j - V_L) - \sum g_k(V_j)(V_j - V_i) + (V_{j-1} - V_j) + g_{j-1,j}(V_{j-1} - V_j) - g_{j,j+1}(V_j - V_{j+1}) \right),$$

where V_L is the resting (leak) conductance and the V_i s are the reversal potentials for ions flowing through the voltage-dependent conductances. The voltage-dependent conductances are the product of a fixed maximal conductance and one or more state variables that describe how the proportion of open channels changes with voltage and time. A separate set of differential equations describes the evolutions of the state variables, generally of the following form:

$$dm/dt = (m_\infty(V) - m)/\tau_m(V),$$

where $m_\infty(V)$ is the steady-state voltage dependence of channel open probability and $\tau_m(V)$ is the voltage-dependent time constant. Channels can

also be gated by internal calcium (or sodium), and in these cases additional differential equations are needed to represent the buffering, extrusion, and diffusion of calcium (or sodium).

Early Models of Action Potential Generation and Repetitive Firing

Dodge and Cooley (1973) adapted the Hodgkin and Huxley (1952) description of the gating of the sodium (Na) and potassium (K) conductances underlying the action potential in squid axons to model the generation of action potentials in spinal motoneurons. The motoneuron was represented as a series of cylindrical compartments representing the proximal axon and soma, and

the dendritic tree was represented as an equivalent cylinder divided into 30 compartments. The model provided a good match to experimentally recorded action potentials and somatic voltage-clamp recordings when Na and K channels were confined to the soma and axon initial segment. In addition, in order to match the experimental data, the voltage dependence of sodium channels on the initial segment was shifted to 10 mV more hyperpolarized than those on the soma, and the densities of Na and K channels on the initial segment were roughly nine- and six-fold times those on the soma. The increased density and lower threshold of channels on the initial segment are common features of compartmental models of motoneurons (and other neurons as well) and fit well with the available experimental evidence (Bender and Trussell 2012).

Until recently, it was generally assumed that normal motoneuron dendrites are passive, i.e., they have no voltage- or calcium-dependent channels. As described later, it is now clear that motoneuron dendrites have a variety of active conductances. However, even early recordings of motoneuron properties indicated that following axotomy motoneurons develop a number of features, such as all-or-none partial spikes superimposed upon synaptic potentials (Kuno and Llinas 1970), which are consistent with the presence of active dendritic conductances. The input–output properties of motoneurons are also altered following axotomy. In normal motoneurons the relation between injected current and firing rate is composed of up to three linear segments: a shallow primary range at lower levels of injected current and a steeper, secondary range at higher levels, followed in some cases by a shallow tertiary range at the highest levels of injected current (Kernell 2006). Following axotomy, the frequency–current (F–I) relation is characterized by a single linear range whose slope is similar to that of the secondary range in normal motoneurons (Heyer and Llinas 1977).

Traub and Llinas (1977) explored the potential mechanisms underlying the differences in repetitive firing in normal and axotomized motoneurons using compartmental models of varying complexity, ranging from a single cable representation of

motoneuron dendrites to up to four branching dendrites. An essential feature of all of the models was the inclusion of a slow potassium conductance underlying the medium-duration afterhyperpolarization (mAHP). This conductance is activated by the influx of calcium through calcium channels that are opened during the spike. Both the calcium (Ca) and calcium-activated potassium channels (KCa) were placed in compartments corresponding to the proximal dendrites, and Na channels were extended to the proximal dendrites to provide sufficient depolarization to activate the calcium channels. The authors examined the effects of several different spatial distributions of Na and KCa channels on model behavior and found a range of distributions that could reproduce the F–I behavior of normal and axotomized motoneurons. Secondary range firing resulted from a decrease in action potential-induced dendritic depolarization at higher levels of injected current, resulting in a decrease in KCa activation. The behavior of axotomized motoneurons was reproduced by lowering the Na density on the proximal dendrites (leading to secondary range firing at low levels of injected current) and putting hot spots of Na channels at $0.6\text{--}0.7\lambda$ from the soma. The distal Na hot spots mediated local spikelike depolarizations in response to synaptic inputs that propagated decrementally to the soma, leading to the spikelike partial responses superimposed on the synaptic potentials recorded at the soma.

Although the mechanism for partial responses proposed by Traub and Llinas (1977) is consistent with the available experimental evidence (Sernagor et al. 1986), secondary range firing does not seem to depend upon a saturation or reduction of the KCa-mediated mAHP (Schwindt and Calvin 1973). More recent compartmental models based on an alternative mechanism of secondary range firing are considered later.

Synaptic Integration in Passive Dendritic Trees

Both cable models and models with a detailed representation of the dendritic tree have been

used to investigate the relation between the structure and specific membrane properties of motoneuron dendrites and the delivery of current from dendritic synapses to the soma. The best-studied synaptic input to spinal motoneurons is the monosynaptic excitatory input from primary muscle spindle (Ia) afferents. Somatic recordings of excitatory postsynaptic potentials (EPSPs) evoked by electrical stimulation of multiple Ia afferents (composite Ia EPSPs) or from the stretch-evoked activation of single Ia afferents (unitary or single-fiber Ia EPSPs) provided a number of lines of evidence that the synaptic terminals of Ia afferents are distributed widely across the dendritic trees of motoneurons (see Burke 1967, and references therein). Single-fiber Ia EPSPs exhibit a wide variety of shapes that can be quantified by plotting the EPSP width at half amplitude (half-width) versus the time to peak. EPSPs with short times to peak and half-widths were presumed to arrive from proximal synapses, whereas distal synapses were thought to underlie those with long time to peak and half-widths. Simulations with a 10-compartment cable model (Rall et al. 1967) could reproduce the experimentally recorded range of EPSP shapes if it was assumed that single Ia afferents gave rise to a number of synaptic terminals at different distances from the soma, an assumption that was later validated by experimental evidence (Burke and Glenn 1996). This model was also able to account for a number of other experimental findings related to the summation of Ia composite EPSPs, their sensitivity to changes in somatic membrane potential and the ability to detect changes in membrane impedance during the EPSP.

The acquisition of detailed anatomical data on the structure of motoneuron dendrites and the projection of single Ia afferent fibers have guided the development of models that provide a much more precise representation of the structure and specific membrane properties of motoneuron dendrites as well as the spatial distribution of Ia afferent synaptic terminals. Detailed models of reconstructed spinal motoneurons have shown that the experimentally recorded voltage responses to pulses and steps of current injected into the soma can only be reproduced if the

specific membrane resistivity is lower in the soma than in the dendrites (Clements and Redman 1989; Fleshman et al. 1988). Although part of this decrease in somatic resistivity may arise from the leak induced by penetration of the soma with a sharp electrode, this is unlikely to be the only factor contributing to variations in membrane resistivity (see Sect. 3.3.2 in Powers and Binder 2001). Unfortunately, there are a number of different spatial distributions of specific membrane resistivity that can reproduce the experimental data; for example, a step distribution (low in the soma and high and uniform in the dendrites) and a sigmoidal distribution (resistivity rises as a sigmoidal function of distance from the soma) give equally good fits to the experimental data. Somewhat surprisingly, when Ia afferent terminals are distributed onto the models in accordance with the available anatomical data, the step and sigmoidal models give equally good fits to the experimentally recorded EPSPs (Segev et al. 1990). Nonetheless, the spatial distribution of voltage changes produced by activating Ia afferents will depend upon the exact spatial distribution of specific membrane resistivity; this may be particularly important when considering how synaptic inputs are modified by voltage-dependent dendritic conductances.

Limited Charge Transfer in Passive Dendritic Trees

Although analysis based on both cable theory and compartmental models indicates that a significant fraction of the charge entering through even the most distal synapses on motoneurons can reach the soma, that situation changes as more and more synapses are activated. The total conductance of a patch of membrane (in the absence of voltage-dependent conductances) is the sum of the resting conductance and the conductance contributed by activated synapses, and even at relatively low levels of synaptic activation, the total conductance begins to be dominated by the synaptic conductance term (Barrett 1975). This increased conductance together with a decrease in driving force as the membrane is depolarized toward the synaptic reversal potential reduces the amount of synaptic

charge reaching the soma. Barrett (1975) concluded that physiological levels of activation of excitatory input to motoneurons could deliver enough current to produce high rates of repetitive discharge, but recent simulations using detailed compartmental models suggest that this may not be the case.

Korogod et al. (2000) calculated synaptic charge transfer for synapses throughout the dendritic tree in detailed compartmental models of reconstructed motoneurons at different levels of tonic synaptic input (simulated by changing the effective membrane resistivity). In models of cat spinal motoneurons, all of the synapses exhibited high transfer effectiveness (i.e., they transmitted at least 50 % of their charge) at rest. However, at high levels of tonic synaptic activity, only the most proximal synapses were effective. Cushing et al. (2005) used compartmental models of reconstructed motoneurons to explicitly estimate the total amount of synaptic current that could be delivered to the soma during increasing activation of excitatory dendritic synapses. The relation between the effective synaptic current (i.e., the portion of current that reached the soma) and the level of excitatory drive was highly nonlinear, due to increases in membrane conductance and decreases in synaptic driving force as increasing numbers of synapses were activated. The effective synaptic current produced by high-frequency (100 Hz) activation of all of the excitatory synapses was well below that needed to maximally drive motoneurons. This result fits with the experimental finding that the effective synaptic currents produced by high-frequency activation of various peripheral and descending inputs to motoneurons were rather modest (Powers and Binder 2001).

Repetitive Firing and Synaptic Integration in Motoneuron Models with Active Dendritic Trees

Many of the early experimental studies of synaptic integration and repetitive firing in motoneurons were based on recordings obtained in anesthetized animals. An alternative preparation is the unanesthetized, decerebrate animal, which

has been used for over a century to study spinal and postural reflexes. In this preparation, the cerebrum is removed under anesthesia, rendering the animal insensate, obviating the need for further anesthetic. In the absence of anesthetic and inhibitory inputs from the cortex, monoaminergic neurons in the brainstem that project to the spinal cord exhibit tonic activity. This tonic monoaminergic drive facilitates the activation of a number of voltage-sensitive channels, including those present on motoneuron dendrites (Heckman et al. 2003). Under these conditions, motoneurons exhibit a number of behaviors that are not observed in anesthetized preparations, and these same behaviors occur in *in vitro* preparations in the presence of monoamines (Heckman et al. 2003). These behaviors include the following: (1) bistable discharge, the motoneuron continues to discharge after the cessation of a brief excitatory stimulus; (2) hysteresis, in response to a triangular injected current waveform, the motoneuron stops discharging at a lower level of injected current than is required to recruit the motoneuron on the ascending limb of the command; and (3) voltage-dependent synaptic amplification, excitatory synaptic currents are increased with depolarization. All of these behaviors are thought to be mediated by persistent inward currents (PICs) generated primarily by low-threshold calcium channels on the dendrites (Heckman et al. 2003).

PIC-mediated behaviors can be replicated by a variety of compartmental models that place the spike-generating (Na and K) conductances on or near the soma compartment and PIC-generating conductances on the dendrites. These include two-compartment models (Booth et al. 1997; Kim and Jones 2010; Venugopal et al. 2011), cable models (Carlin et al. 2009; Powers et al. 2012a,b; Shapiro and Lee 2007), and detailed compartmental models (e.g., Bui et al. 2006; Elbasiouny et al. 2005, 2006). The consensus view based on these simulations is that the bistable behavior and hysteresis observed in somatic recordings arise from a plateau depolarization in the dendrites following voltage-dependent activation of the PIC. The PIC acts in combination with the leak conductance (and probably voltage-dependent K conductances) to give

rise to a dendritic current–voltage (I–V) relation that is N-shaped, reflecting the contribution of the leak current at hyperpolarized voltages (leading to a positive slope in the I–V relation) and the predominance of the PIC at intermediate voltages (leading to a negative I–V slope), followed by a predominance of outward currents at more depolarized voltages (Heckman et al. 2003). This N-shaped relation has two stable steady-state voltages: one near the resting potential and one corresponding to a depolarized plateau potential. Bistable behavior occurs when injected or synaptic current produces a dendritic plateau that persists when the excitatory input stops, since the plateau depolarization represents a stable state. In response to a triangular injected current waveform, the onset of the dendritic plateau leads to an increase in the slope of the F–I relation (secondary range firing), followed by a decrease in slope (tertiary range firing) once a stable plateau is reached (Elbasiouny et al. 2006; Powers et al. 2012a,b). Hysteresis in the F–I relation occurs because the site of the dendritic plateau is at a significant electrical distance from the soma, so that the plateau is turned off at a lower somatic voltage that was required to initiate the plateau.

Simulations based on detailed compartmental models suggest that the best matches to the experimental data are obtained when the Ca channels responsible for the plateaus are restricted to a relatively narrow range of distances centered at roughly 0.5λ away from the soma, although the exact length and location of these dendritic “hot spots” depend somewhat on which types of experimental data (both electrophysiological and anatomical) are used to constrain the models (Bui et al. 2006; Elbasiouny et al. 2005; Grande et al. 2007b). The presence of multiple hot spots of Ca channels may allow motoneurons to amplify synaptic inputs in a graded manner as synaptic input is increased, since the effective thresholds for activating Ca channels may vary along the dendritic tree as a result of variations in the local geometry (Bui et al. 2006; Elbasiouny et al. 2006; Carlin et al. 2009). A nonuniform distribution of Ca channels also can allow differential amplification of different synaptic inputs, with increased amplification occurring as the spatial

distributions of synaptic terminals and Ca channels show increasing overlap (Bui et al. 2008; Grande et al. 2007a).

There is also evidence that dendritic (as well as somatic and axonal) Na channels contribute to PICs and synaptic amplification (Heckman et al. 2003; Powers et al. 2012a,b). One intriguing possibility, based on a recent simulation study with a two-cable compartmental model, is that bistable firing and synaptic amplification arise in different parts of the dendritic tree with different PIC-generating channels (Shapiro and Lee 2007). In this model, all-or-none plateau generation by Ca channels gives rise to bistable behavior, whereas graded activation of Na channels produces synaptic amplification.

Although there is not enough experimental and simulation data to specify the spatial distribution of Na and Ca channels mediating PIC, the data do support the idea that most of the PIC is derived from dendritic channels (Heckman et al. 2003), and this has important implications for the synaptic control of motoneuron firing rate. Since most of the synaptic input is on the dendrites, the dendritic plateaus have a lower threshold for activation (as measured at the soma) when driven by excitatory synaptic input than by current injected into the soma (Bui et al. (2006) in fact used experimental data of this type to set their channel distributions). As a result, in both cable (Powers et al. 2012a,b) and detailed compartmental models (Elbasiouny et al.), an increase in excitatory drive can lead to a rapid increase in firing rate as soon as the motoneuron starts to fire (secondary range firing), followed by a much shallower increase in rate with further increases in excitation (tertiary range firing). Similar patterns of firing are seen in human motor units during slowly increasing isometric contractions, supporting the hypothesis that PICs provide an important contribution to motoneuron discharge during a variety of motor behaviors (Heckman et al. 2008).

Limitations

As is true of almost all compartmental models, the experimental data is not sufficient to constrain the

parameters (channel properties and channel distribution) of compartmental models of spinal motoneurons. This limitation is particularly severe for motoneuron models due to the lack of direct dendritic recordings and the limited immunocytochemical data on the dendritic distribution of different channel types. As a result, the actual spatial distribution of a particular channel may be significantly different from the one that provides the best fit to experimental data for a given model, since the optimal distribution is likely to vary with the channel properties and the presence of other channels. Nonetheless, the spatial separation of spike-generating and plateau-generating conductances is a common feature of many different types of compartmental models of spinal motoneurons and at this point appears to provide a fairly accurate representation of a range of motoneuron behaviors.

Definition

Dopamine (DA) is a neuromodulator released by midbrain neurons with widespread projections

throughout the brain. Dopaminergic modulation has diverse effects on cellular, motor, and cognitive functions, including reinforcement learning, working memory, and attention. Dysregulation of dopamine also plays a central role in the breakdown of these functions in disorders such as Parkinson's disease and schizophrenia.

Detailed Description

Dopamine Basics

DA is a neuromodulator released by neurons in two nuclei of the midbrain: the ventral tegmental area (VTA) and the substantia nigra pars compacta (SNc). The axons of these neurons project to a large number of cortical and subcortical areas. Prefrontal cortex, motor cortex, and the striatum are among the most densely innervated areas. DA release tends to be fairly homogeneous across DA neurons, by virtue of electrical coupling between the axons of adjacent neurons, which induces highly synchronous firing. As pointed out by Paul Glimcher, these properties suggest that DA neurons “cannot say much to the rest of the brain but what they say must be widely heard” (Glimcher 2011).

DA affects its targets primarily by two classes of receptor – D1 and D2 – and the distinct properties of these receptors have functional consequences which are discussed below. D2 receptors tend to be activated earlier, and at lower concentrations, than D1 receptors (Lapish et al. 2007; Schultz 2007). As a consequence, D2 receptors are more sensitive to phasic (transient) DA release than D1 receptors, with the opposite pattern for tonic (background) DA release (Grace 1991). D1 and D2 receptors also have different postsynaptic effects: D1 receptor activation increases both NMDA (excitatory) and GABA (inhibitory) currents, whereas D2 receptor activation decreases them (Trantham-Davidson et al. 2004).

Reinforcement Learning Models

One of the most influential hypotheses about DA is that it plays an integral role in a system that learns to predict future reward. This hypothesis

can be formalized in terms of the theory of reinforcement learning (RL) first developed in computer science (Sutton and Barto 1998). At each time t the agent occupies a state s_t (e.g., the agent's location or the surrounding stimuli) and receives a reward r_t . The goal of an RL system is to estimate the *expected discounted future return*, or *value*, of visiting a sequence of states starting in state s_t :

$$V(s_t) = E \left[\sum_{k=0}^{\infty} \gamma^k r_{t+k} \right], \quad (1)$$

where γ is a *discount factor* that accounts for the fact that distal rewards are less valuable than proximal rewards. The expectation E represents an average of the quantity inside the brackets over stochastic sequences of states.

If we make certain assumptions about the environment (specifically, that it is a *Markov decision process*; see Sutton and Barto 1998), then the value can be estimated by a simple learning rule known as *temporal difference learning*:

$$\hat{V}(s_t) \leftarrow \hat{V}(s_t) + \alpha \delta_t, \quad (2)$$

where α is a *learning rate* and δ_t is a *prediction error* defined as:

$$\delta_t = r_t + \gamma \hat{V}(s_{t+1}) - \hat{V}(s_t). \quad (3)$$

Intuitively, if the prediction error is greater than zero, then more reward was received than was predicted, and hence $\hat{V}(s_t)$ is increased. If the prediction error is less than zero, then $\hat{V}(s_t)$ is decreased. Another implication of this learning rule is that prediction errors will gradually propagate backwards in time as values at earlier time points come to reflect reward received at later time points.

Schultz et al. (1997) observed that the phasic firing of DA neurons in an appetitive conditioning experiment was conspicuously consistent with a hypothetical prediction error. In these experiments, a conditioned stimulus (CS, e.g., a tone) is repeatedly followed by an unconditioned stimulus (US, e.g., juice reward). Schultz et al. noticed that DA firing increased in response to an

unexpected reward (e.g., in early training trials). After multiple training trials, if the reward is delivered following the CS, then DA firing is at baseline following reward delivery but increases following the CS onset. In this case, the reward is expected and hence the prediction error at the time of reward is zero, whereas the prediction error at the time of the CS is greater than zero due to the temporal propagation described above. Finally, if the reward is omitted following the CS, DA firing pauses (decreases below baseline), consistent with the occurrence of a negative prediction error.

In addition to its role in predicting reward, DA plays an important role in selecting actions to increase reward. For example, electrophysiological studies have shown that DA responses to reward are sensitive to actions (Morris et al. 2006; Roesch et al. 2007), and DA receptor antagonism in the striatum suppresses the initiation of reward-seeking actions (Berridge and Robinson 1998). According to RL theory, there are a number of ways to use prediction errors to estimate the value of actions, some of which have been integrated into models of DA (e.g., Frank 2005; Houk et al. 1995; Montague et al. 1996; Suri and Schultz 1998).

Since the seminal work of Schultz et al. (1997), the prediction error theory of DA has been corroborated by converging evidence from humans and other animals (see Glimcher 2011 for a review). At the same time, it is clear that such a simple theory is unable to account for many of the complexities of DA function. These lacunae have stimulated a number of significant extensions of the theory, some of which are described below. Interestingly, these extensions mirror the technical development of RL theory in computer science. Biological and artificial agents face similar challenges in optimizing reward – and may have even arrived at similar solutions.

One development of the prediction error theory concerns the phasic DA firing in response to novel stimuli (e.g., Horvitz et al. 1997). The original prediction error theory fails to anticipate this finding, since novelty does not by itself predict reward. However, as pointed out by Kakade and Dayan (2002), novelty responses can be rationalized by considering the problem of optimizing

reward. All agents face a dilemma between *exploiting* the currently best option and *exploring* other options that might be potentially better (Cohen et al. 2007). One way to encourage exploration is by initializing the values of all states to be greater than zero. As shown by Kakade and Dayan, this has the effect of generating positive prediction errors when these states are visited for the first time, consistent with the DA novelty response.

A second development has been to incorporate timing variability and partial observability into the TD model (Daw et al. 2006). The original prediction error theory (Montague et al. 1996; Schultz et al. 1997) used a delay line to represent different temporal epochs as distinct states. Daw et al. (2006) replaced the delay line with two assumptions: (1) States are occupied for some random amount of time before a transition occurs (timing variability); and (2) states are not directly observed, but must be inferred from noisy sensory data (partial observability). Daw et al. showed that these extensions could account for a number of timing properties of phasic DA firing. For example, if a reward is delivered early or late, a phasic DA burst is observed (Hollerman and Schultz 1998), contrary to the delay line model, which predicts a negative prediction error (i.e., a pause in firing). The Daw et al. model correctly predicts a positive prediction error, because it infers that a transition to the “reward state” has occurred early or late.

A third development of the theory concerns the role of tonic DA. It has long been recognized that tonic levels of DA appear to be regulated independently of phasic levels (Grace 1991). In particular, increased tonic DA has been associated with the invigoration of behavior (Schultz 2007), and the depletion of tonic DA results in a loss of vigor (Salamone et al. 2001; Sokolowski and Salamone 1998). To account for these observations, Niv et al. (2007) proposed that tonic DA signals an estimate of an environment’s average reward. When the average reward is high, it is rational for an agent to respond more vigorously (since more reward can be collected), whereas when the average reward is low, the energetic costs may outweigh the benefits of responding. This model predicts not only a lower rate of

responding with depleted tonic DA but also a longer latency to respond, consistent with experimental evidence (Denk et al. 2005).

A fourth development has been to integrate the prediction error theory into more biologically detailed models of RL in the basal ganglia. For example, Frank (2005) proposed a model in which DA differentially affects the “direct” and “indirect” pathways of the basal ganglia. The direct pathway striatal neurons in the direct pathway primarily express D1 receptors, whereas striatal neurons in the indirect pathway primarily express D2 receptors. The net effect of DA in the striatum is to increase activity in the direct pathway and suppress activity in the indirect pathway, resulting in disinhibition of action selection in the frontal cortex via modulation of basal ganglia output pathways. One consequence of this differential effect is that neurons in the direct pathway undergo long-term potentiation following a DA burst, whereas neurons in the indirect pathway undergo long-term depression. Another contribution of this model is a division of error-driven learning into positive and negative components: D1-expressing neurons learn more from positive prediction errors, whereas D2-expressing neurons learn more from negative prediction errors. Thus, the model of Frank (2005) provides a neurally plausible mechanism by which DA can influence action selection in corticostriatal circuits.

Gain Modulation and Working Memory

The sensitivity of a neuron to stimulation can be enhanced by the application of DA, without changing the spontaneous firing rate (Clarke et al. 1987; Foote and Morrison 1987). In other words, DA increases the signal-to-noise ratio of a neuron. Servan-Schreiber et al. (1990) introduced a connectionist implementation of this idea by positing that DA increases the gain β of a sigmoidal activation function:

$$a = \frac{1}{1 + e^{-\beta x - b}}, \quad (4)$$

where x is the synaptic input of the neuron, b is the baseline membrane potential, and a is the firing

rate. This basic schema for dopaminergic gain modulation has been reproduced in much greater biological detail by a number of authors (e.g., Durstewitz et al. 1999; Moyer et al. 2007).

An important function of gain modulation is to support active maintenance in working memory: If a group of neurons are recurrently connected to form an attractor network, increasing the gain will increase the stability of high activity states (i.e., actively maintained memories) while suppressing low activity states corresponding to spontaneous background activity. Consistent with this idea, DA appears to play an important role in supporting active maintenance of working memory representations in the prefrontal cortex (Cohen et al. 2002).

DA has been hypothesized to play a complementary role in updating working memory (Braver and Cohen 1999; Durstewitz et al. 1999; O'Reilly and Frank 2006). According to these models, a phasic burst of DA acts as a “gating” signal, transiently amplifying afferent inputs while suppressing local inhibitory signals. The effect of this gating signal is the encoding of afferent input into the current attractor state. O'Reilly and Frank (2006) have proposed a biologically detailed refinement of this idea, whereby “stripes” in the prefrontal cortex (groups of neurons connected to distinct areas of the basal ganglia). Levitt et al. (1993) encode representations in working memory that are updated by phasic DA bursts. This model uses an RL mechanism to learn when to gate, providing a link to the models of corticostriatal plasticity described above.

How can the active maintenance and updating roles of DA be reconciled? One suggestion is that these roles are mediated by different receptors. Specifically, Cohen et al. (2002) have suggested that phasic DA activity primarily affects updating via D2 receptors, whereas tonic DA activity primarily affects active maintenance via D1 receptors. These two modes interact, with tonic DA inhibiting phasic DA by regulating presynaptic autoreceptors (Grace 1991). This hypothesis is consistent with the observation that prolonged pharmacological elevation of tonic DA results in perseverative and stereotyped behavior (Arnsten

1998; Sawaguchi and Goldman-Rakic 1991), which could arise from a failure to update due to reduced phasic DA.

Computational Modeling of Dopamine-Associated Disorders

The models reviewed above furnish a set of hypotheses about the etiology of psychiatric disorders arising from DA dysfunction. This section focuses on the two most well-studied examples: schizophrenia and Parkinson's disease.

A number of authors have proposed that many cognitive deficits in schizophrenia can be explained by a breakdown in the regulation of gating (Braver and Cohen 1999; Durstewitz and Seamans 2008; Frank 2008; Waltz et al. 2007). The gain modulation view leads Braver and Cohen (1999) to propose that reduced prefrontal DA in schizophrenics results in a lower signal-to-noise ratio; combined with noisier DA signaling, this produces gating of irrelevant information into working memory and can cause psychotic episodes in schizophrenia. Another view, proposed by Frank and colleagues (Frank 2008; Waltz et al. 2007), is that striatal D1 receptor function is compromised in schizophrenia, resulting in impaired learning from positive prediction errors but spared learning from negative prediction errors.

The model of Frank and colleagues also sheds light on the cognitive deficits in Parkinson's disease (Frank 2005; Moustafa et al. 2008b; Wiecki and Frank 2010). Unmedicated patients with Parkinson's disease appear to be better at learning from negative outcomes compared to positive outcomes, and this pattern is reversed by DA medication (Cools et al. 2006; Frank et al. 2004; Moustafa et al. 2008a). Frank et al. explained these findings in terms of the effects of DA levels on D1 and D2 receptors in the striatum: Depleted DA in unmedicated patients results in D2 dominance (as in schizophrenia), whereas elevated DA in medicated patients results in D1 dominance. This account may explain the nature of cognitive deficits following DA medication, such as failures to avoid non-rewarding or punishing stimuli

(Cools et al. 2006; Frank et al. 2004; Moustafa et al. 2008a) and susceptibility to pathological gambling and addiction (Dagher and Robbins 2009).

In addition to these cognitive deficits, Parkinson's disease is associated with bradykinesia, an overall slowing of movements, and this deficit is relieved by DA medication. However, Parkinson's patients can learn to make movements at a task-specified velocity and with the same level of accuracy as controls; the key difference is that Parkinson's patients take longer to reach the performance criterion (Mazzoni et al. 2007). The tonic DA model of Niv et al. (2007) offers a perspective on these findings: since tonic DA is reduced in Parkinson's disease, the average reward will be perceived as lower, thus reducing the opportunity cost of not responding. Thus, bradykinesia may actually reflect an optimal decision by the motor system based on incorrect information about average reward provided by tonic DA (Niv and Rivlin-Etzion 2007).

Computation with Population Codes

E. Paxon Frady¹ and William B. Kristan²

¹Department of Neurosciences, UC San Diego, La Jolla, CA, USA

²Division of Biology, UC San Diego, La Jolla, CA, USA

Definition

Population coding is a computational theory postulating that information is represented and processed by a large number of neurons. In such a coding scheme, each neuron on its own encodes only a small amount of the information that is distributed across the population. Population coding provides robustness, because even if individual neurons are noisy or fail altogether, the population code still processes information effectively.

Detailed Description

Fundamentals of Computation

To understand how a population code computes, we will first start by describing the basics of computation by analyzing silicon-based computers. There are two essential ingredients to

computation: representation and transformation. Information in computers is represented using discrete binary digits, called bits. A bit is often thought of as a “yes” or “no” response or a “1” or “0”. A bit represents two states and is the simplest form of information. A computer is built by utilizing a large number of bits to represent information. The number of elements that can be represented grows exponentially with the number of bits that are used. Eight bits (a “byte”) can represent up to 256 (2^8) different values. Large numbers are represented by more and more bits: an integer is typically represented by 32 bits, and a “double” is a decimal number that is represented by 64 bits. A computer can represent anything by using more and more bits of information. A 2-h movie, for example, is currently represented with about 8 billion bits.

Computation is in essence the transformation of information from one representation to another. For instance, a computer represents – or “encodes” – each letter in this text by a byte (8 bits). For you to read this text, the computer must transform each letter into an image, which is made of pixels that are also represented by bits. The computer transforms the byte that represents each letter into a different sequence of bits that represents the pixel colors. The specific rules of the transformation are called the “algorithm.” The monitor then “decodes” the bits that represent the pixel colors and creates an image. A computer can perform “universal” computation, which means that it has the ability to transform any string of bits into any other arbitrary string of bits. This ability is what makes a computer so powerful, because it can transform any type of information in one representation into any other representation.

The brain, too, must represent a large number of variables produced by the sensory environment or intrinsic states. To perform their functions, neurons in the brain must be able to encode, transform, and decode this information. However, unlike the bits on a computer, neurons are intrinsically noisy. The failure of a single bit in a computer could have catastrophic effects on the entire system, but by design there is virtually no noise in a computer, so these types of failures are rare. Biological systems, on the other hand, have a

great deal of noise of many sorts – both from the intrinsic properties of the component neurons and from ongoing neural activity from sources other than the signal of interest. The neurons must perform their computations in the face of many potential failures caused by this noise. The brain appears to solve this noise problem by distributing information across a large population of neurons. Having more neurons entails robustness to the encoded information, because a large number of independent neurons represent the information. By spreading the information about different variables across many neurons, very little information is lost if a single neuron misfires or even dies.

Theoretical work in systems neuroscience has developed the “population coding” framework of neural computation, based on this premise that information is processed across a large population of neurons. Population coding computes differently than a computer, but it still must perform the same fundamental operations of information processing: representation and transformation. The brain receives information from the outside world and must represent this information in the activity of neurons. The brain then transforms this information in different brain regions to other representations that are useful for perception or behavior. For instance, to grab a baseball, your brain transforms visual information that is stored in an eye-centered coordinate system into a body-centered coordinate system. The same information is stored in both coordinate systems, but with different representations. The motor cortex then uses the body-centered coordinate system to generate a motor sequence that contracts and relaxes the correct muscles to reach out while opening the hand and then stop the reaching and close the hand as it envelopes the baseball. For the brain to perform such a behavior, it must have a representation of all the relevant information, as well as the ability to transform one representation into another.

Representation of Single Variable in Population Codes

The first step for a population code is to represent information through the activity of neurons.

A good way to understand how a population code can represent information is to decode a single variable from neural responses. A classic example of population coding is provided by determining how a simple cell in visual cortex responds to bars oriented at different angles. A given simple cell responds maximally to a bar that is oriented at the neuron’s “preferred” angle, but this neuron also responds to orientations that are close to this preferred angle. The relationship between the stimulus and the firing rate of the neuron creates the neuron’s “receptive field,” which peaks at the preferred angle and decays as the stimulus angle moves away from the preferred angle. The receptive field is typically a bell-shaped curve, often taken to be Gaussian for nonperiodic variables and a cosine function for periodic variables (Deneve et al. 1999).

A large number of neurons make up the population, where each neuron has its own receptive field. The preferred orientations of each neuron are spread out across the full stimulus space. Figure 1a shows several example receptive fields from eight different neurons; each bell-shaped curve is the receptive field of a different neuron. These receptive fields partially overlap and are centered at different preferred angles. When a stimulus is presented, all neurons respond based on their receptive fields. When an oriented bar is presented that has an angle of $\theta = 90^\circ$, then several neurons with preferred orientations close to 90° will fire (Fig. 1b). The closer the neuron’s preferred orientation is to 90° , the higher the neuron’s firing rate, but noise can make the firing rate variable for a given stimulus presentation. The activity of the population is described by

$$r_j = f_j(\theta|\Theta_j) + \epsilon \quad (1)$$

where r_j is the firing rate of neuron j , Θ_j is the preferred orientation of neuron j , f_j is a function that describes the neuron’s receptive field, and ϵ is noise. This is the “standard model” of population coding.

There are various approaches used to come up with an estimate, $\hat{\theta}$, of the orientation of the stimulus encoded by the firing rates of the population of neurons. All approaches obtain an

Computation with Population Codes, Fig. 1 The standard model of population coding. (a) A population of neurons have receptive fields that are sensitive to different orientations. Each bell-shaped curve is from a different neuron, and the neuron's preferred orientations are spread out across the stimulus space. Y-axis: spikes per second. (b) When an orientation of $\theta = 90^\circ$ is presented, the

neurons respond based on their receptive fields shown in a. (c) The population vector estimator is a voting method that decodes the orientation from the neural activities by fitting a cosine function to the responses. (d) The maximum likelihood estimator fits a template derived from the receptive field shapes (From Deneve et al. 1999)

estimate by computing a function from the activity across the population R , where $R = (r_1, r_2, \dots)$. Because of noise, the response across the population varies during different presentations of the same identical stimulus. This variability means that the estimate, $\hat{\theta}$, is a random variable. Different techniques for decoding the estimate from the population activity have been developed, each with different tradeoffs: in bias (whether the $\hat{\theta}$ is right on average), variance (how close $\hat{\theta}$ is to θ on average), computational efficiency, and biological plausibility (Pouget et al. 1998).

One interpretation of the population code representation is that each neuron “votes” for its preferred stimulus. Such schemes are typically computationally efficient and biologically plausible, but have higher variances than other decoding methods (they are only optimal under specific conditions as discussed below). Three

commonly used voting schemes are the following.

Population Vector Estimator (PVE)

Bar orientation is a spatially periodic variable, and the PVE decodes such periodic variables by fitting a cosine function (Fig. 1c) to the activity patterns, R :

$$\hat{\theta}_{\text{PVE}} = \text{phase}(z) \quad (2)$$

where

$$z = \sum_j r_j e^{i\theta_j} \quad (3)$$

Optimal Linear Estimator (OLE)

Because the PVE works only for periodic variables, other measures must be used for

nonperiodic variables. A standard algorithm for decoding a nonperiodic variable from a population code is the OLE:

$$\hat{\theta}_{\text{OLE}} = \sum_j \Theta_j r_j \quad (4)$$

Center of Mass Estimator (COM)

A simple extension of the OLE, the COM can account for the background firing (one form of noise) by comparing the neural responses when the stimulus is presented to the background rate and when the stimulus is absent:

$$\hat{\theta}_{\text{COM}} = \frac{\sum_j \Theta_j (r_j - b)}{\sum_j (r_j - b)} \quad (5)$$

where b is the spontaneous activity of the neurons. All three of these estimators are “voting methods,” because each spike from a neuron is like a vote for that neuron’s preferred stimulus feature, and the estimate is a simple combination of all of the votes. Unlike these voting methods, other estimators can decode the population activity optimally, which means the variance of the estimate is minimized and there is no bias. These estimators are less biologically plausible, however, and less computationally efficient than the voting methods.

Maximum Likelihood Estimator (ML)

This estimator finds the value of θ that maximizes the conditional probability of the population response, $P(R|\theta)$, and is optimal when θ is uniformly distributed:

$$\hat{\theta}_{\text{ML}} = \arg \max_{\theta} P(R|\theta) \quad (6)$$

The ML estimator is similar to the PVE in that it is effectively fitting a template to the population response (Paradiso 1988) (Fig. 1d). However, the PVE assumes that the shape of the template is a cosine, whereas the ML derives the template directly from the receptive fields of the neurons, which means that the decoder must have knowledge of the receptive field shapes of the encoding neurons. This may be a biological implausibility, but it is also possible that the receptive field shapes are learned over time (Sanger 2003).

Maximum a Posteriori Estimator (MAP)

This estimator is an extension of the ML estimator that can incorporate the prior distributions of R and θ . The MAP estimate maximizes the full posterior distribution of the encoded variable, $P(\theta|R)$, which is derived from the conditional probability through Bayes’ theorem:

$$\hat{\theta}_{\text{MAP}} = \arg \max_{\theta} P(\theta|R) \quad (7)$$

$$P(\theta|R) = \frac{P(R|\theta)P(\theta)}{P(R)} \quad (8)$$

This is a useful modification if certain values of θ are more likely than others, e.g., if horizontal orientations are seen more frequently than vertical orientations. If the prior distribution is flat – meaning that all values of θ are equally likely – then the MAP estimate is identical to the ML estimate.

High-Dimensional Population Codes

The activity of a population of neurons can be considered to form a high-dimensional response space: two neurons would form a two-dimensional space (a plane), three neurons would form a three-dimensional space, etc. If the activity of three neurons is plotted as the x , y , and z coordinates in a three-dimensional Cartesian system, then a particular stimulus activates these neurons in a particular firing pattern, which would correspond to a point, called the “population vector,” in three-dimensional space. Each additional neuron would add a dimension to this response space. As the firing rate of neuron j increases, the population vector would move up in the j th dimension. If we had ten neurons representing the 1-dimensional orientation, then each presentation of a particular orientation would activate the ten neurons in a specific way that would correspond to a population vector in the 10-dimensional response space. Each orientation would cause a different pattern of activation, which would correspond to a different population vector in the 10-D space. Together, the responses to all possible orientations would form a 1-D “manifold” (a curvy line) in the 10-D response space.

In addition to representing information about one stimulus variable, a population of neurons can encode multiple variables simultaneously. A signal could have several feature dimensions, all of which are encoded by the brain. For instance, a population of neurons could simultaneously encode both the orientation and the thickness of a bar stimulus. In this population, each neuron would have a two-parameter receptive field that has both a preferred orientation and a preferred thickness:

$$r_j = f_j(\theta, \phi | \Theta_j, \Phi_j) + \epsilon \quad (9)$$

where Φ is the thickness of the bar and Φ_j is the thickness preferred by neuron j . In this representation, each combination of orientation and thickness would correspond to a single point in the high-dimensional response space (with each dimension again corresponding to the activity of one neuron). All possible combinations of bar orientation and bar thickness would form a 2-dimensional manifold (a curvy plane). In one direction along this manifold, the information about orientation is represented, and in another direction information about thickness is represented. In general, the population can encode multiple dimensions of the stimulus, where each neuron can be sensitive to any combination of stimulus dimensions:

$$r_j = f_j(\theta, \phi, \psi, \dots | \Theta_j, \Phi_j, \Psi_j, \dots) + \epsilon \quad (10)$$

An individual neuron can have a preference for an arbitrary combination of each of the stimulus dimensions. The preferred orientation and thickness of a given neuron can be chosen independently. For instance, a neuron with a preferred orientation of $\Theta_j = 90^\circ$ could be just as likely to respond to a thick bar as a thin bar.

The information about a particular feature of the stimulus does not necessarily correspond to the firing of a particular neuron. In the population code, the neurons represent stimuli through their joint activities. When representing multiple stimulus dimensions, the neurons are activated by all features of the stimulus with different strengths.

The orientation of a stimulus would thus be only one of many components of the response for a given neuron. The information about orientation is encoded in the combination of activities across the population. This can be thought of as a particular direction in the high-dimensional space, but not as the firing of a particular neuron.

Just as adding more neurons adds more dimensions to the population code, adding more features to the stimuli would increase the number of dimensions in the manifold representing those features. In general, the larger the number of dimensions (i.e., neurons), the larger the number of features that a particular neuronal population can represent. This relationship between the number of neurons and the number of features that can be encoded requires a consideration of “basis sets.”

Basis Sets

For the same neurons to encode more than one feature, the activity of the neuronal population must create a “complete basis set” for these features. To understand what such a requirement means, consider a particular set of neurons with receptive fields that respond to both orientation and thickness, but these receptive fields are actually perfectly correlated: neurons that prefer 90° orientations also prefer thick bars, and neurons that prefer 0° also prefer thin bars. If the receptive fields are correlated in such a way, then there are different combinations of orientations and thicknesses that activate the population in exactly the same way. If the population response is the same to two different stimuli, then there is less information about the stimulus available in the activity. Technically, this inability of the population to fully encode the two features arises because we have intentionally made the receptive fields “linearly dependent.” For the neurons to represent all the dimensions of the stimulus, they must form a complete basis of the stimulus space: the manifold determined by the neurons’ firing rates in the response space must have as many dimensions as the number of features. Because we have made the receptive fields perfectly correlated,

every combination of thickness and orientation no longer forms a 2-dimensional manifold, but instead forms a 1-dimensional manifold. Every point in the 1-dimensional manifold represents different combinations of the two dimensions, which means that the information about both features is not present in the population activity.

To form a complete basis of a stimulus space with d dimensions, there must be at least d neurons with receptive fields that are “linearly independent.” This means that no receptive field could be made out of a linear combination of the other receptive fields. The number of stimulus dimensions that a population code could possibly represent is less than or equal to the number of neurons. Typically a signal can be fully characterized by only a few features, and the number of neurons responding to a stimulus is usually much greater than the number of stimulus dimensions. If there are d stimulus dimensions, and N neurons in the population, and $N > d$, then the population code is a d -dimensional manifold in an N -dimensional space. To form a complete basis of a d -dimensional stimulus, there must be at least d neurons with receptive fields that are linearly independent. Not all of the neurons need to be linearly independent, however; with N neurons, some of the receptive fields can be linear combinations of others, as long as there is a subset of at least d linearly independent receptive fields.

If the stimulus dimensions (d) are low compared to the number of neural dimensions (N), the neurons can form an “overcomplete basis set” of the stimulus space. There are at least d neurons with linearly independent receptive fields in an overcomplete basis set, but the other neurons can be linearly dependent. The overcomplete basis gives robustness to the population code because redundant information about the stimulus is duplicated across many neurons in the N -dimensional space. Even if one of the N neurons completely failed, the $N-1$ neurons would still form a complete basis of the d -dimensional stimulus space, and no information about the stimulus would be lost. An interesting feature of this robustness is that none of the $N-1$ receptive fields needs to be exactly the same as the neurons that failed. The information carried by the failed neuron is also

represented by some linear combination of the $N-1$ neural responses. This property means that no two neurons are necessarily “redundant” – every neuron could have a unique response to a stimulus – but there is redundant information in the population vector. This redundancy helps the neuronal population maintain all of the information even in the presence of large amounts of noise.

The receptive field functions (f_j) play a critical role in the formation of a basis set. The receptive field shapes considered so far are Gaussian (aka, bell-shaped curves), because these types of functions match many biological receptive fields and because these types of functions are capable of forming a basis set. There are other types of receptive field functions (such as sigmoids or threshold-linear) that can also form basis sets, and it is possible to have different types of basis functions together in a single population code. The key property is that the basis set must be able to represent (or closely approximate) any type of nonlinear function by a linear combination of the basis functions:

$$g(\theta) = \sum_j w_j f_j(\theta | \Theta_j) \quad (11)$$

where w_j are the coefficients and $g(\theta)$ is some nonlinear function. This requirement of a basis set is similar to the decomposition of a signal by a Fourier transform, where a linear combination of sines and cosines can closely approximate any nonlinear function. Some receptive field functions do not have this property. For instance, if all the receptive fields were linear, then any linear combination of them would also be linear. This means that nonlinear functions cannot be fully represented, which means that a population code based entirely on linear receptive fields could not fully represent any signal.

Nervous systems can utilize the population coding framework beyond representing extrinsic features of the stimulus. The brain must represent intrinsic information about decisions and motor-commands as well. The nervous system of the leech has provided insights into how the same population of neurons can encode different

modalities of information. The leech has a very simple nervous system, where the activity of a significant fraction of cells (>100) can be recorded simultaneously with voltage-sensitive dyes (VSDs). These recordings show that almost every cell in the leech nervous system is multifunctional: each neuron responds to many different stimuli and during several different behaviors. In effect, each neuron has a high-dimensional receptive field that is sensitive to many of the sensory, motor, and intrinsic variables. Neurons in the leech encode the sensory environment using a population code. The local bend response is a reflex in which the leech bends its body away from a stimulus. Local bending requires

information about the stimulus location to be propagated through the nervous system. The neurons involved in this behavior have overlapping receptive fields, each with preferred touch locations, and encode the information about touch location just like the orientation information in the standard model (Lewis and Kristan Jr 1998; Fig. 1a). Neurons are also encoding information about the motor patterns. For instance, virtually all the neurons that respond while the leech swims also respond while the leech crawls (Briggman and Kristan Jr 2006; Fig. 2a). Swimming and crawling are both oscillatory behaviors, and many of the neurons' voltages oscillate with the muscle contractions at different phases

Computation with Population Codes, Fig. 2 Populations encode multiple modalities of information. (a) Neurons that oscillate with the swimming and crawling behaviors were observed with voltage-sensitive dyes. Virtually all neurons are multifunctional: those involved in swimming were also involved in crawling. (b, c) Image of the dorsal side of the leech ganglion where neuron somas are shown as circles. Neurons involved in crawling (b) and swimming (c) are colored based on the relative phase of their oscillations. (d) The swimming and crawling central pattern generators (CPG) are encoded as different population vectors in the high-dimensional neural space. The population begins at an initial rest state and then makes an excursion to one of the CPGs after a stimulus. (e) The first three principal components of neural responses. This allows the high-

dimensional neural space to be reduced to 3 dimensions, which can be visualized. (f) Trajectories of the neural responses in PCA space during swimming and crawling behaviors (left). The black dots indicate equally spaced intervals in time. These behaviors can be predicted from the population response using linear discriminant analysis, which chooses the direction that maximally separates the population vectors during the two behaviors (arrow). The decision to swim or crawl can be determined before the motor patterns start (right): the traces show the firing of several motor neurons during swimming (blue) or crawling (red). In one outlier, the population vector appeared to head in the swim direction, but changed course and went to the crawl pattern (green) (From Briggman et al. 2005; Briggman and Kristan Jr 2006)

(Fig. 2b, c). There is no correlation between the phase at which a neuron oscillates during swimming and the phase at which it oscillates during crawling. This may be a consequence of the population forming a complete basis of all the motor patterns, because uncorrelated responses can arise from linearly independent receptive fields.

The swim and crawl motor patterns are represented as different population vectors in the high-dimensional response space of neural activity (Fig. 2d). The swim motor pattern is off in one direction, and the crawl motor pattern is off in another. To visualize the population code recorded through VSD imaging, the high-dimensional neural activity was reduced to three dimensions using principal components analysis. Each principal component corresponds to different combinations of activity patterns across all the neurons (Fig. 2e). The combinations of activity that are most correlated are chosen as the first three principal components, and the population vector can be visualized as a point in three-dimensional space. By plotting the population vector over time, the two behaviors can be distinguished in the neural activity (Fig. 2f). In fact, the neural activity predicts the future behavioral state before the swim or crawl behavior actually begins. If the leech is stimulated at a particular site, it “chooses” to swim or crawl with equal probability. This decision can be decoded from the population activity before the motor pattern can be seen. The information about the decision is encoded by the same population of neurons and can be decoded as a particular direction in the high-dimensional space. By finding the point in time where the population vectors during swim and crawl separate, the decision direction can be decoded as the linear discriminant that maximally separates the two classes of behavior. The decision direction is actually a different direction than the information about either motor pattern (Briggman et al. 2005). This shows that the leech nervous system encodes all of the pertinent information as different directions along a manifold in high-dimensional space, regardless of whether the information is sensory, motor, or intrinsic.

Transformations with Population Codes

Each area of the brain represents information using its own population code by combining information from the population codes of its inputs. Decoding a population code with an estimator is a strategy for an experimentalist to get an understanding of how information is represented by neuronal activity. In the brain, however, the stimulus dimensions are never directly extracted from a population code of neural activity. Instead, one population code is mapped directly onto another population code. This mapping is still effectively an estimation problem, because the direct mapping is equivalent to decoding the relevant information from the inputs and then encoding them into the local code.

Mapping one population code onto another requires nonlinear transformations. An excellent example of this problem is the transformation of a retinotopic map onto a head-centered map (Pouget and Sejnowski 1997; Fig. 3). As the eyes move around, neurons that receive information from the retina have receptive fields that move with the eyes. These neurons encode the visual scene in retinotopic coordinates. Another population of neurons encodes the position of the eyes. With the information from these two populations, the brain can encode the visual input in reference to the head position, which would be useful if an object was moving towards your head and you wanted to move your head out of the way. The goal is to transform the population code in the retinotopic coordinates into a population code in head-centered coordinates by combining the retinotopic information with the eye position information. For simplification, we will consider a model of only the horizontal spatial dimension of the stimulus, x . In this model, each neuron in the retinotopic population has a receptive field that is based on where the stimulus falls on the retina. For these receptive fields, the relevant stimulus dimension is the position on the retina, r_{x_i} , and each neuron has a preferred retinal position (Fig. 3a). A second population encodes the position of the eyes, e_x (Fig. 3b). The eye position neurons were given sigmoidal receptive fields, which were chosen because of their

Computation with Population Codes, Fig. 3 Transformation of population codes. (a) A population of neurons form a retinotopic map of the visual world, with individual neurons having receptive fields based on where the stimulus falls on the retina (r_x). (b) Another population of neurons encode the position of the eyes (e_x). (c) The hidden layer combines information from the retinotopic map and eye position units and forms a population code that is a complete basis set of the input

information. (d) The head-centered reference frame can be decoded from the hidden layer with a linear transformation. (e, f) The receptive field of a neuron in the hidden layer (same as panel C) has a receptive field that is gain modulated by the eye position units. This allows the hidden layer to form a complete basis set of the inputs. (e) Full 2-D receptive field. (f) Slices of the receptive field shown in black from (e) (From Pouget and Sejnowski 1997)

biological relevance; each of these neurons has a different inflection point (similar to a preferred stimulus) in their receptive fields, and they too form a population code.

To combine the information from the retina (r_x) and the eye position (e_x), an intermediate (“hidden”) layer was added (Fig. 3c) that forms a population code to represent the combined information about retinal activity and eye position. The key to the transformation was to make the population code of the hidden layer have a complete basis set of the information from both input populations. This projected the two dimensions of the stimulus (retinal position and eye position Fig. 3a, b) onto a 2-dimensional manifold

in high-dimensional space (Fig. 3c). This transformation allowed the relevant dimension of head-centered coordinates (Fig. 3d) to be a simple linear combination of the population code formed in the hidden layer, which could easily be read out by the next neuronal population. The advantage of using a population code with a complete basis set is that any reference frame is just a linear combination away.

In fact, information about eye position, head position, body position, joint position, etc. can all be combined into a single population code. With such a code, different motor systems can read out the information about visual space with different reference frames all from the same population

(Pouget and Sejnowski 1997) with just a simple linear transformation. Further, the information about each reference frame can be decoded by these motor systems in parallel, because the population code is representing all of the necessary information simultaneously.

The key to forming this basis set was to find how the activity in the two population codes should be combined. It is standard procedure that synaptic connections can compute linear transformations of the inputs $\left(r_j = \sum_i w_{ij} r_i\right)$, i.e., the synaptic strengths multiply the input firing rates to produce the downstream firing rates. But this modification alone was not sufficient to form a complete basis set of the data; gain control was also needed. Gain control is a scaling of the post-synaptic firing rate and is seen in many different biological neural circuits. Gain control is a non-linear operation, which meets the necessary conditions for forming a basis set (other nonlinearities are also possible, but gain control is the most biologically plausible (Pouget and Sejnowski 1997)). Figure 3e, f shows how neurons in the hidden layer are gain modulated by the eye position, where the receptive field shape is maintained, but the amplitude is altered. These neurons are inspired by the activity of neurons in parietal cortex.

The mechanism of gain control in neurons is still controversial. Early studies postulated that shunting inhibition could be the mechanism of such multiplicative transformations (Blomfield 1974; Vu and Krasne 1992). Shunting inhibition alters the resistance of the neuron by opening inhibitory channels with a reversal potential that is the same as the resting potential. Changing the resistance of the neuron scales the voltage (and thus the firing rate) through Ohm's law ($V = IR$). More recent studies have suggested that this mechanism is not sufficient when spiking dynamics are considered and that shunting inhibition acts additively (Holt and Koch 1997). Many alternatives use neural circuitry to implement gain control (Baca et al. 2008; Salinas and Abbott 1996). However, shunting inhibition is receiving renewed interest as the mechanism for gain

control, as models show that adding noise (Doiron et al. 2000; Chance et al. 2002) or using multi-compartmental neurons (Capaday and van Vreeswijk 2006) can implement multiplicative operations in spiking neuron models.

Population Coding in Time

Many signals that the brain processes change in time. This temporal information can also be encoded by population codes. To encode temporal information, the receptive fields must also vary in time. An illustration of how temporal population coding is implemented by the nervous system comes from studies of olfactory processing in the insect antennal lobe. While randomly puffing pulses of odor, several neurons were recorded as they responded to the fluctuating odor stimulus. Neurons respond with different activity patterns during such an odor stimulus; some neurons respond immediately when the odor turns on and then go silent, some neurons stay on while the odor is present, and still other neurons respond only when the odor turns off. The firing rates of these neurons were approximated by a "linear-nonlinear model" and closely matched the recorded rates. This model found a "temporal receptive field" that describes a preferred temporal fluctuation in the odors where the neuron fires maximally. Just like receptive fields considered before, temporal fluctuations in the stimulus that are close to the preferred temporal fluctuation also cause the neuron to fire. The temporal receptive field integrates the fluctuation pattern of the odor stimulus over time (this is the linear part of the model), and this sum is then passed through a nonlinear function (which is a threshold-linear filter).

The temporal receptive fields found for all of the neurons can be well described by only two main components (Fig. 4a). These components are determined by normalizing the responses and calculating the principal components across time for all of the temporal responses of the neurons. Each neuron's receptive field is effectively explained as a linear combination (i.e., a weighted

Computation with Population Codes, Fig. 4 Population coding in time. (a) The first two principal components (PC1, PC2) of the temporal receptive fields of many neurons in the insect antennal lobe. (b) The coefficients of the first two components for each receptive field. The receptive fields are spread out uniformly around the unit circle as different combinations of the two main components. The colors are based on the angle of the coefficients around the circle (Φ). (c) All normalized receptive fields plotted and sorted vertically based on the angle from (b). (d, e) A simple model of the insect antennal lobe population code. (d) The signal ($s(t)$) is encoded by the responses of a population of neurons ($r^{(n)}(t)$) with different temporal receptive fields and a threshold-linear filter. (e)

The receptive fields were chosen based on eight different combinations of the principal components derived in (a). (f) Responses of four antennal lobe projection neurons (PN1-4) to a step of odorant (top, gray-shaded area), compared with the responses of the model (bottom) that shows similar patterns of activation. (g) The population vector trajectories in PCA space of the recorded neurons from (f) (top) when two different odors were presented. The population vector encodes the odorant presence and recent fluctuation history. The model neurons show a similar pattern (bottom). B indicates the baseline when no odor is present; FP indicates fixed points of the population vector when different odors are present (From Geffen et al. 2009)

sum) of just two components. Figure 4b shows the weights of the two components that best match the derived filters from the data, where the weights for each component are spread out at every angle, mainly along the edge of the unit circle. Figure 4c shows the shapes of all of the filters sorted based on the angle, which shows how the filters for all the neurons vary smoothly as combinations of the two components. These neurons represent temporal variations of the odor signal as a two-dimensional manifold in the high-dimensional neural space. The neurons' receptive fields are spread out almost uniformly, which creates an overcomplete basis set that is minimally redundant and maximally robust. These types of receptive fields allow the neurons to encode a representation of some temporal history of the signal in the population code.

This encoding of temporal history in the population response can be seen in a simple model of these neurons (Fig. 4d). In the model, a population of neurons are randomly given one of the eight receptive fields made out of different combinations of the two main components (Fig. 4e). When the population is given a step odor stimulus, the neurons respond differently based on their receptive fields. Just like the responses seen in the antennal lobe, the model neurons go through different fluctuations when the stimulus comes on and when it goes off (Fig. 4f). The stimulus information is encoded as a point in the high-dimensional activity space, which in this case moves in time (Fig. 4g). Before the onset of the odor step, the population is at some equilibrium (denoted as B). After the step, the population vector makes a rapid excursion from baseline and eventually reaches a fixed point (FP), which indicates that the firing rates have reached a steady state. When the odor is turned off, the population vector leaves the fixed point, makes another excursion, and settles back to the original baseline. If a different odor is given, then the neurons progress through a similar pattern, but along a completely different trajectory.

Each point along these trajectories encodes the recent history of the odor fluctuations. Since the

odor filters are responsive only to a window of a few seconds, the information in the population code contains only a few seconds of history. At the fixed point after the odor turns on, the population vector represents the presence of a particular odor and the fact that the odor has not changed in the last few seconds. During the excursion, the population vector continuously encodes the odor presence and the sudden change in odor that occurred when the odor step turned on. Different odor fluctuations would move the population vector along different trajectories in the high-dimensional space, and the recent history of the stimulus fluctuations can be decoded by the immediate position of the population vector.

Alterations in the neural responses over longer timescales would be required to encode a longer history of temporal information. Other types of temporal fluctuations seen in nervous systems may be serving this purpose. A full range of different time scales could be implemented by various neural mechanisms. For instance, adaptation or neuromodulators can encode information on the order of seconds, short-term plasticity could be involved in representing information on the order of tens of seconds, and long-term plasticity could encode even larger temporal scales.

Conclusion

Population coding is a powerful framework for neural computation. By spreading information across a large population of neurons, the brain solves many of the problems posed by biology. Noise is mitigated by coding information in the joint activities of many neurons, instead of individual neurons that can easily fail. Further robustness is achieved by coding with an overcomplete basis set, which contains redundant information that can compensate for information lost due to noise. An overcomplete basis set enables a population of neurons to represent all of the features of the stimulus, the intrinsic states, and/or motor activity as well as the recent history of these states simultaneously. This facilitates parallel

processing from downstream systems, since they can decode different reference frames from the same population. Population codes can be arbitrarily transformed into other representations and combined with information from other population codes in a biologically plausible manner. Population coding is a promising theoretical basis for universal computation in the nervous system and a necessary foundation for generating the wide variety of perceptual, cognitive, and behavioral states seen in the brain.

Computation with Serotonergic Modulation

Matthew Lewis

Cornell University, Ithaca, NY, USA

Synonyms

5-hydroxytryptamine (5-HT)

Definition

Serotonin is an aminergic neuromodulator found throughout nervous systems of invertebrate and vertebrate animals. Serotonergic modulation of neural circuits plays an important role in a multitude of neural functions ranging from motor control, memory systems, decision-making, and sensory processing.

Detailed Description

Introduction

Serotonin (5-HT) is an ancient neuromodulator fundamentally tied to the evolution, development, and optimal function of the nervous system of animals. 5-HT and serotonergic receptors (5-HTRs) are found throughout the body and influence almost every aspect of animal physiology, ranging from autonomic functions such as cardiovascular/smooth muscle tone and thermoregulation to higher-level processes such as sensory processing, cognitive control, memory, and emotion. The role of 5-HT is complex and multifaceted, in part due to a variety of properties of the

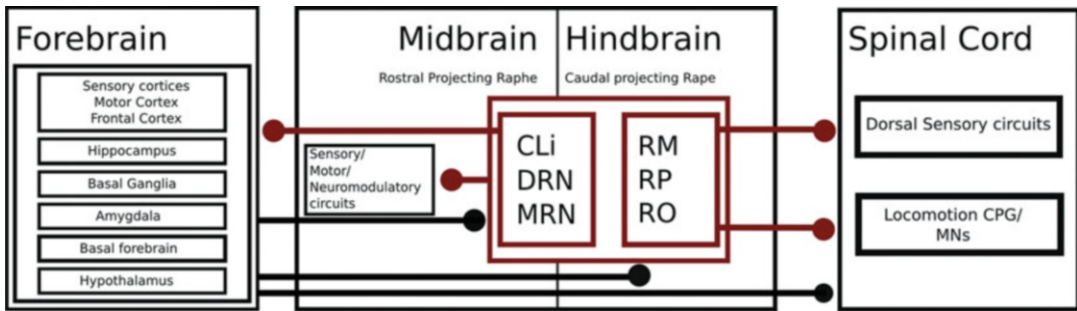

serotonergic system. In both invertebrate and vertebrate species, serotonergic fibers project throughout the nervous system releasing 5-HT at synapses and non-synaptically through a process known as volume transmission, a common feature of neuromodulatory transmission (Zoli et al. 1999; Dayan and Huys 2009). There are many different types of 5-HTRs (at least 17 different receptors within humans), many of which exert opposing and/or complementary effects on neuronal physiology and act on the order of milliseconds to minutes (Bockaert et al. 2006). Lastly, in recent years, there has been a growing understanding of the functional heterogeneity of serotonergic neurons in central nervous system, suggesting the existence of specific serotonergic subsystems, which modulate specific neural structures and behavior in a context- and brain state-dependent manner (Hale and Lowry 2011). Given the biochemical and behavioral complexity of the serotonergic system, it is difficult to discern an underlying principle that governs its role, as has been attempted for other neuromodulators (Doya 2002; Montague et al. 2004; Ashton-Jones and Cohen 2005; Bouret and Sara 2005; Hasselmo and Sarter 2011).

Early neurophysiology experiments performed in invertebrate preparations have shown that 5-HT modulates the intrinsic membrane properties of neurons, altering action potential waveforms and membrane conductances, through the activity of 5-HTR-dependent signaling pathways (Kleinhaus and Angstadt 1995; Katz 1998). Through these same pathways, 5-HT has been shown to play a role in the modulation of synapses, where it is capable to augment or attenuate the strength of synapses within a neural circuit. While 5-HT alters the properties of neurons and synapses within particular neural circuits, it also plays a role in the interactions between distinct neural structures, modulating the relative strengths of opposing circuits, leading to changes in brain state and production of adaptive behaviors (Brezina 2010; Dayan and Huys 2009). Most recently, computational neuroscientists, influenced by computational theories of learning and decision-making, have argued that given the widespread presence of 5-HT in the vertebrate

brain, 5-HT might act as a global signal, reporting behaviorally relevant state information (i.e., reward, hunger, arousal, punishment) to the rest of the brain, facilitating the formation of both aversive and appetitive cognitive states. Finally while many scientists have proposed many theories for a single function of 5-HT (Soubri  1986; Deakin and Graeff 1991; Jacobs and Fornal 1999; Tecott 2007; Cools et al. 2007; Dayan and Huys 2009), it is important to note that 5-HT does not act in a “neurochemical vacuum” and there are many important interactions between the serotonergic and other neuromodulatory systems both at the cellular and network level (Katz and Harris-Warrick 1990; Daw et al. 2002; Marder and Thirumalai 2002). I will here briefly review the main functions ascribed to 5-HT modulation in (1) rhythmic motor networks and (2) modulation of sensory systems. Note that this is by no means a complete or exhaustive review of 5-HT function in the central nervous system, but rather an overview of the best described roles of 5-HT modulation.

5-HT and Rhythmic Motor Networks

Serotonin plays a prominent role in the initiation and coordination of rhythmic motor behaviors in both invertebrate and vertebrate nervous systems (Jacobs and Fornal 1993; Katz 1998; Jordan and Slawinska 2011). Rhythmic motor behaviors (i.e., swimming, breathing, walking) are driven by the activity of biological neural networks known as central pattern generators (CPGs). These networks generate stable, repetitive motor outputs even in the absence of sensory feedback or extrinsic cues. Neuromodulators alter CPGs by altering both intrinsic membrane properties and synaptic interactions among neurons within the CPG. Modulatory inputs play an essential role in normal network function. In many experimental systems, the removal of neuromodulatory inputs through a variety of methods can significantly impair or completely abolish rhythmic motor activity (Harris-Warrick 2011). In vertebrates, 5-HT plays an important role in the generation of rhythmic locomotion

Computation with Serotonergic Modulation, Fig. 1 Schematic of the mammalian 5-HT system. Serotonergic neurons (shown in red) are restricted to the midbrain and hindbrain, where they are divided into two distinct populations. A rostral-projecting group projects to the forebrain and midbrain structures (caudal linear nucleus, *CLi*; dorsal raphe nucleus, *DRN*; median raphe nucleus, *MRN*). The majority of serotonergic axonal fibers travel to the forebrain through the forebrain bundle, a

major axon tract of the mammalian brain. Serotonergic neurons are found throughout the forebrain where they modulate sensory processing, motor cortex, and cognitive function. A caudal-projecting group projects to hindbrain and spinal cord structures where it modulates transmission of sensory signaling, locomotor central pattern generators (CPGs), and autonomic functions (raphe magnus, *RM*; raphe pallidus, *RP*; raphe obscurus, *RO*)

behaviors (Fig. 1). In the neonatal rodent spinal, bath application of 5-HT is reliable and commonly used method to induce in vitro fictive locomotion. Several 5-HT₂ or 5-HT₇ receptors prevent the initiation of fictive locomotion following brainstem stimulation. Conversely pharmacological activation of 5-HT₂ and 5-HT₇ receptors induces rhythmic outputs within the spinal cord that resembles electrically driven locomotion. Within spinal CPG neurons, 5-HT alters intrinsic membrane properties through the modulation of particular membrane currents. 5-HT lowers the voltage threshold of activation of the hyperpolarization-activated cation current (I_h) and persistent sodium current (I_{NaP}), inducing a depolarization from rest (Jordan and Slawinska 2011). Computational modeling of the spinal CPG suggests that the spinal locomotion is organized by the activity of two interconnected levels of a half-center oscillator, a rhythm-generating layer and a pattern-forming layer (McCrea and Rybak 2008). 5-HT is thought to modulate excitatory and inhibitory neurons within these two functional layers, providing tonic excitatory drive and important flexibility to perform coordinated rhythmic movements (Harris-Warrick 2011; Jordan and Slawinska 2011).

Serotonergic Modulation of Sensory Systems

Just as in the motor networks mentioned above, neuromodulators also continuously modify sensory circuits to appropriately guide behaviors (Birmingham and Tauck 2003; Hurley et al. 2004; Devore and Linster 2012). Neuromodulatory neurons effecting sensory processing may either be intrinsic to an affected sensory circuit or located in distal brain regions providing centrifugal inputs to many brain regions (sensory or non-sensory) concurrently. Rather than transmitting information about ongoing stimuli, neuromodulatory inputs instead are thought to dynamically filter neural representations in a manner related to environmental events and/or the brain's internal state (Hurley et al. 2004; Devore and Linster 2012). 5-HT is an important mediator of these functional changes.

In vertebrates, the majority of sensory circuits receive centrifugal serotonergic inputs from the median raphe (MRN) and dorsal raphe nuclei (DRN) located along the midline of the brainstem. Interestingly, DRN neurons receive inputs from many sensory processing regions, including the retina and vestibular nuclei (Kawano et al. 1996; Ye and Kim 2001). It should be noted that the majority of DRN inputs are not from sensory

structures but instead from other raphé nuclei, midbrain, and cortical structures (Hornung 2010). Tonic DRN activity is tied to the phase of the sleep-wake cycle, with activity highest during the waking state. Compared to alert waking states, DRN neurons show decreased tonic activity during quiet waking states, even less activity during slow-wave sleep, and are completely silent during rapid-eye movement (REM) sleep (Jacobs and Fornal 1999). DRN neurons also respond transiently to particular types of sensory stimuli (Heym et al. 1982; Ranade and Mainen 2009). Lastly, recent work has suggested that DRN neurons may be transmitting signals related to features of behavioral paradigms such as reward, aversion, and executive control (Miyazaki et al. 2012; Nakamura 2013).

5-HT has been shown to modulate sensory responses across a number of neural structures across species and sensory modalities (Andersen and Dafny 1982; Kloppenburg and Erber 1995; Mooney et al. 1996; Hurley and Pollak 1999; Xiang and Prince 2003; Kloppenburg and Mercer 2008; Dacks et al. 2009). In many regions of the brain, patterns of neuromodulatory input are highly heterogeneous and differentially target particular neuron types within specific sensory circuits (McLean and Shipley 1987; Klepper and Herbert 1991; Mooney et al. 1996; Kang et al. 2001; Paspalas and Papadopoulos 2001). Through complex innervation patterns and the multitude of 5-HTRs expressed within sensory circuits, 5-HT induces a variety of effects on sensory representations from gross attenuation (Petzold et al. 2009) or enhancement (Hurley and Pollak 2001; Deemyad et al. 2013) to alteration of receptive field structure (Hurley and Pollak 1999; Dacks et al. 2009) and changes in neural sensitivity to environmental cues (Kloppenburg and Mercer 2008; Yokogawa et al. 2012).

Computational Analysis of Rodent Spinal CPG

William Erik Sherwood
University of Utah, Salt Lake City, UT, USA

Definition

The production of patterned locomotor output by the rodent neuromuscular system is regulated by the central pattern generator(s) of the spinal cord. The rodent spinal CPG is capable of producing a wide range of gaits, and in particular the default “fundamental locomotor rhythm” of walking.

Fictive locomotor experiments and transgenic rodent lines have produced a wealth of information about the neuronal constituency and synaptic organization of the rodent spinal CPG, but many neuronal subpopulations have yet to be identified and the full synaptic architecture is far from being definitively mapped out. A few mathematical and computational models have been proposed which (1) integrate experimental results into a unified, interrogable conceptual framework and (2) enable the testing of various hypotheses of CPG organization in silico. The ultimate goal of computational modeling and analysis of the rodent spinal CPG is to link specific network structures and intrinsic neuronal properties to experimentally observed features of locomotor output.

Detailed Description

Background

In order for it to walk effectively, a rodent's forelimb and hind limb muscles must repeatedly flex and contract in the correct sequence and with the correct timing (onset and duration) of flexion and contraction. In rodents and other mammals, the basic patterning of such locomotor activity is generated and maintained by the neuronal networks in the spinal cord, which are most likely organized into one or more central pattern generators (CPGs).

Early experiments with decerebrate cats established that higher order input from the brain is not needed for locomotion: Cats whose brainstems have been transected at the level of the mesencephalic locomotor region (MLR) will walk with the proper gait and speed when placed on a moving treadmill. (If the brainstem is transected above the MLR, the cats will walk spontaneously; if the transection is made below the MLR, the electrical or pharmacological stimulation of the brainstem is required to produce walking.) Thus, the circuitry which patterns neuromuscular activity for walking, as well as other basic gates such as hopping and jumping, must be located below the brainstem in the spinal cord.

The closely related phenomenon of "fictive locomotion" has been studied in experiments on rodents. In these preparations, the whole spinal cord is removed from the animal and then stimulated either electrically or using neuromodulatory agents, e.g., serotonin, NMDA, dopamine, or acetylcholine. The stimulation evokes neural activity among the interneurons and motoneurons of the cord, and the observed firing patterns correspond closely to the activity patterns observed in intact, locomoting animals, as explained below. Motoneuron activity is measured at the dorsal roots, the proximal ends of bundles of motoneuron axons that innervate the muscles of the intact animal, and typically occurs in rhythmic bursts. The motoneurons (and interneurons) active during locomotion are located in the lower thoracic and lumbar spinal segments; those active during hind limb movement are found in lumbar segments L1–L6, with the strongest coordinated activity often measured from L2 and L5. Firing of L2 motoneurons corresponds to hind limb flexor muscle activity, while firing of L5 motoneurons corresponds to hind limb extensor muscle activity.

The phasing of motoneuron bursts – between the L2 and L5 segments and between the left and right sides of each segment – takes one of four forms: total (contralateral) intra- and (ipsilateral) intersegmental synchrony, (contralateral) intrasegmental alternation with (ipsilateral) intersegmental synchrony, (contralateral) intrasegmental synchrony with (ipsilateral) intersegmental alternation, and simultaneous (contralateral) intrasegmental alternation with (ipsilateral) intersegmental alternation. These modes correspond to tonic-clonic seizing, rhythmic left-right alternation, hopping, and fictive locomotion (in experimental preparation) or walking (in the intact animal). This last mode, simultaneous ipsilateral flexor-extensor antisynchrony and contralateral flexor-flexor/extensor-extensor antisynchrony, is also called the fundamental locomotor rhythm of the spinal locomotor CPG. Since the rhythmic neural firing patterns evoked in fictive locomotor experiments occur in the absence of sensory feedback, it may be inferred that the neural programs for basic locomotor gates, and the mechanisms for switching between them, are encoded in the circuitry of the spinal locomotor CPG.

Neurobiology of the Rodent Spinal CPG

The neurons of the rodent spinal CPG may be divided into four major functional classes: motoneurons (MNs), ipsilateral coordinating interneurons (ICNs), commissural interneurons (CINs), and rhythmogenic interneurons (RGNs).

Motoneurons directly innervate the flexor or extensor muscles on a single side of the animal, and their axons form the ventral roots of each spinal segment. Though they act primarily to excite muscular contraction, they may also limit their own firing by exciting Renshaw cells which in turn inhibit the motoneurons. The most significant flexor-related motoneuron clusters are found in L1 and L2, and the main extensor-related motoneuron clusters are located in L5 and L6.

The rhythmogenic interneurons appear to be a heterogeneous group of interneurons which act in different ways to support the rhythmic (oscillatory) drive that underlies the locomotor pattern. Neither the composition nor the location of the RGN population is known with much certainty. Each lumbar segment has some rhythmogenic capacity, as does each side of a given segment, but some segments exhibit stronger rhythmogenic activity than others in fictive locomotion experiments. Some RGNs, i.e., those in the Hb9 and V2a subclasses, may be able to burst endogenously and may thereby effect direct rhythmic excitation of MNs. But quite likely there are other, as yet unidentified, subpopulations of RGNs, perhaps organized in a half-center oscillator configuration, which contribute to the generation of the rhythmic motor pattern.

Experiments using transgenic rodent (mainly mouse) lines have provided the most detailed picture of the intra-segmental connectivity of the spinal cord. A small number of ICN subpopulations have been identified to date, including the Renshaw cells already mentioned, as well as Ia, V1, and V2b interneurons. These interneurons act via inhibition to enforce alternation between extensor-associated and flexor-associated neuron groups on a single side of the midline. Some subtypes, in particular V1, help regulate locomotor speed.

The axons of commissural interneurons cross the midline of the spinal cord and may synapse

onto neurons in the same spinal segment or several segments away. CINs mediate all cross-cord communication and play a central role in coordinating the rhythmic alternation of flexion and extension between the left and right sides. As with the ICNs, our most detailed knowledge of spinal cross-cord connectivity comes from transgenic rodent studies. The main CIN pathways are inhibitory: some run from L1, L2, and L3 to L4, L5, and L6, and vice versa, while others connect opposite sides of the same spinal segments. Presumably all of these connections work to enforce the contralateral flexor-flexor and extensor-extensor antisynchrony needed for walking. Some experimental work has also indicated that there are excitatory CIN connections within and between segments (e.g., mediated by V0 Dbx1 and V3 interneuron subpopulations), but less is known about them, and the evidence that they play a significant role in cross-cord coordination is indeterminate. It is known that contralateral MNs are the postsynaptic targets of some CINs, but for many CIN pathways the targets are not known precisely, and the overall organization of CIN connections is only incompletely understood.

Computational Models

Computational models of the rodent spinal CPG have two main goals: (1) to integrate the myriad experimentally determined neurobiological details into a unified, comprehensible framework and (2) to help researchers investigate hypotheses regarding CPG organization under simulated experimental conditions. There are also two competing imperatives which inform the construction of any computational neuroscience model: comprehensive inclusion of all known experimental data in the pursuit of biological realism and the simplification of messy details, imperfect data, and biological complexity in order to improve model comprehensibility and to make model analysis tractable. Extant models of the rodent spinal CPG resolve the tension between these competing aims at different balance points.

Coupled Cell Networks

Most simplified are coupled cell network models, originally developed by Golubitsky et al., which are defined solely in terms of generic oscillator cells and their connections (Buono 2001; Buono and Golubitsky 2001; Golubitsky et al. 1999; Stewart et al. 2003). In the locomotor CPG context, they aim to answer the question, given a particular arrangement of (generic) neurons and synaptic connections, which locomotor gaits are even theoretically possible? Few, if any, assumptions are made about the cells' intrinsic dynamics or the properties of the connections. The cell networks' dynamics are described purely in terms of their constituent cells' phases, and model analysis relies on the symmetry properties of the network. This approach is essentially mathematical, rather than computational, and eschews almost all biological details. It is quite powerful, however, in that it can establish definitively the complete set of possible phase relationships which can exist in a network of oscillators with a given symmetric coupling structure. It can also be used to determine whether the set of possible outputs of two different networks is functionally identical. Although real CPGs have many cell types with complicated cellular dynamics, as well as a variety of synaptic and electrical couplings, and may not be fully symmetric, often their structures do appear to conform (at least roughly) to the results of the mathematical theory. Especially relevant to the modeling of the rodent spinal locomotor CPG are results which establish the minimal network structures (minimal in the sense of least number of oscillatory cells and connections) which are capable of producing all known bipedal and quadrupedal gaits. In particular, eight coupled oscillatory cells arranged in two rings of four cells (a two-layer network) are needed to produce all primary and secondary gaits in quadrupeds.

Rybak Et al. Model

Over the past decade, Rybak and collaborators have developed a large-scale model of the mammalian CPG which incorporates a great deal of experimental data from both cat and rodent preparations, achieving remarkable biological realism

at the expense of some analytic tractability (Ivashko et al. 2003; Dietz et al. 2013; McCreary and Rybak 2007; Rybak et al. 2006a, b). The model is discussed in detail in the article (Two-Level Model of Mammalian Locomotor CPG); here we present only a brief summary. The Rybak et al. model comprises a few 100 Hodgkin-Huxley-style model neurons, divided into classes aligned with the rubric of MNs, ICNs, CINs, and RGNs described above. Where possible, the intrinsic properties of the model neurons are tuned to match those of identified subpopulations of the mammalian spinal CPG. Experimental data on synaptic connectivity also inform the model's synaptic architecture. However, some features of the model's neuronal and synaptic components are, of necessity, hypothetical.

The chief distinguishing feature of the Rybak et al. model is its two-layer architecture: there is a clear partitioning of interneuronal subnetworks into a rhythm-generating layer and a pattern formation layer. The rhythm-generating layer has a synaptic architecture that supports rhythmogenesis via a standard half-center oscillator dynamic, but it also includes model neurons capable of intrinsic bursting. The output of the rhythm-generating layer feeds forward (primarily excitation, but also with a few inhibitory pathways) to the pattern formation layer. The pattern formation layer includes reciprocal inhibitory circuits which enhance and modulate the flexor-extensor alternation communicated from the rhythm-generating layer. The output of the pattern formation layer feeds forward to the motoneurons, acting via direct excitation on motoneurons as well as via polysynaptic inhibition. There is no direct pathway from the rhythm-generating layer to the motoneurons. Both the rhythm-generating and pattern-generating layers may receive direct tonic excitation, simulating input from the MLR. In its original incarnation, the model was used to simulate the CPG network of a single hemicord of the decerebrate cat preparation, and it admitted afferent feedback at each neuronal layer. The model was later modified to model the rodent fictive locomotor preparations described above. The modified model includes two hemicord CPG

units connected at the rhythm-generating level via both inhibitory and excitatory CINs, and it omits the tonic drive from the MLR and afferent feedback.

When properly tuned, the Rybak et al. model successfully reproduces the basic fictive locomotor rhythms found in the cat and rodent spinal preparations, with good matches to the oscillation periods and duty cycles recorded in experiments. Perturbation experiments with the model show that it is capable of recovering from phase-resetting perturbations rapidly and with minimal interruption of the locomotor rhythm. Furthermore, the model reproduces the phenomenon of deletions, spontaneous omissions of a motoneuron pool's activity during a phase of the locomotor rhythm when it is normally active. In most cases, deletions do not change the overall phase of the locomotor rhythm once the deleted motoneuron pool rejoins the rhythm, and they are thus termed "non-resetting deletions." A small minority of deletions do lead to a shift in the phasing of the fundamental locomotor rhythm and are called "resetting deletions." The dual layer architecture of the Rybak et al. model can explain the origin of the two types of deletions: failures at the rhythm-generating layer produce resetting deletions, while failures at the pattern-generating layer produce non-resetting deletions.

Sherwood et al. Model

Intermediate in biological realism and analytic tractability is the model of Sherwood et al. for the rodent spinal hind limb CPG (Sherwood et al. 2011). It uses Hodgkin-Huxley-style neurons and dynamic synapses (with parameters and properties parameters similar to those of corresponding cells in the Rybak et al. model), and it is informed by experimental data on the neurobiology of the rodent spinal CPG circa 2008. It was developed, however, with the mathematical results from coupled cell network theory in mind, and to this end it represents various populations of MNs, CINs, and RGNs by single representative model neurons (as per the methods of coupled cell network theory, the ICNs were functionally subsumed into the synaptic connections between the other three categories of

neuron). Furthermore, it is organized as a single layer with multiple symmetries; all synaptic connections known or hypothesized at the time were included. A key departure from conventional CPG architectures (i.e., half-center oscillators) is that each RGN bursts endogenous, so that rhythmogenesis is an intrinsic neuronal property, rather than a network property. In many respects, the Sherwood et al. model is a "minimal" biologically realistic model of the rodent spinal CPG (see Fig. 1).

While it was known from theoretical considerations that such an architecture is capable of producing each of the fictive locomotor gaits seen experimentally, Sherwood et al. sought to investigate how effectively the fundamental locomotor rhythm was achieved by the CPG when starting from an unorganized state, how the CPG responded to perturbations of the locomotor rhythm, and how the distribution of synaptic weights affected these two aspects of CPG output. Emphasis was placed on understanding the role of CINs in organizing simultaneous ipsilateral flexor-extensor antisynchrony and contralateral flexor-flexor/extensor-extensor antisynchrony (the walking rhythm). To this end, they explored the space of symmetric synaptic weightings in the CPG model extensively and also studied the phasing properties of functionally significant subnetworks (related to quotient networks in coupled oscillator theory) of the full CPG model.

Among the findings was that a multitude of synaptic weightings produced functionally equivalent CPG output, echoing results from studies of invertebrate CPGs (cf. Prinz et al. 2004). Strong inhibitory connections were required to produce the fundamental locomotor rhythm, while small amounts of interfering cross-cord excitation could destabilize it. In all configurations leading to the fundamental locomotor rhythm, the model CPG recovered very slowly from perturbations, much more slowly than could be biologically plausible. Analysis of CPG subnetworks revealed that the endogenous bursting properties of the coupled RGNs dominated the phasing and synchronization properties of the CPG network. This was a major cause of the slow network phase resetting in

Computational Analysis of Rodent Spinal CPG, Fig. 1 Diagram of the full CPG model of Sherwood et al. *Flex* flexor, *Ext* extensor (From Sherwood et al. 2011)

response to perturbation. It was surmised that rhythmogenesis by single endogenously bursting neurons was not functionally equivalent to – and was in some way more fragile than – rhythmogenesis by conventional half-center oscillator networks. Subsequent investigation of the phase response properties of endogenously bursting neurons revealed that such neurons have a much richer phase response structure than tonically firing neurons and thus more complicated synchronization behavior in some network architectures, such as that of the Sherwood et al. CPG model (Fig. 1).

Computational Model-Based Development of Novel Stimulation Algorithms

Oleksandr V. Popovych¹ and Peter Alexander Tass^{2,3}

¹Institute of Neuroscience and Medicine – Neuromodulation (INM-7), Jülich Research Center, Jülich, Germany

²Department of Neurosurgery, Stanford University, Stanford, CA, USA

³Department of Neuromodulation, University of Cologne, Cologne, Germany

Definition

In the context of this entry, the model-based development of stimulation algorithms designates a process of creation and computational testing of new techniques for control and modulation of undesirable (pathological) neuronal dynamics. Abnormal brain activity has been observed in several neurological disorders

including Parkinson's disease, essential tremor, epilepsy, tinnitus, and others. Brain stimulation is used for the therapy of patients suffering, for example, from Parkinson's disease, epilepsy, or mental disorders. Brain stimulation is called deep brain stimulation (DBS) if structures deeply inside the brain are targeted, cortical stimulation (intracortical or epicortical) if the electrical contacts of the stimulator are positioned within the cortex or on its surface, or noninvasive transcranial stimulation if the neurons are stimulated by electrical currents induced across scalp by either external magnetic field (transcranial magnetic stimulation, TMS) or electrical current administered via scalp electrodes (transcranial direct-current stimulation, tDCS). Apart from direct brain stimulation, other stimulation forms and targets may also be used, such as spinal cord stimulation (e.g., for the treatment of pain), vagus nerve stimulation (for the treatment of epilepsy), or acoustic stimulation (for the treatment of tinnitus). Novel, model-based approaches, which use methods from synergetics, nonlinear dynamics, and statistical physics to specifically restore brain function and connectivity, demonstrate how insights into the dynamics of complex systems contribute to the development of novel therapies.

Detailed Description

In the nervous system synchronization processes play an important role, e.g., in the context of information processing (Singer 1989) and motor control (Andres and Gerloff 1999). However, pathological, excessive synchronization may strongly impair brain function and is a hallmark of several neurological disorders like Parkinson's disease (PD), essential tremor, epilepsy, and tinnitus (Alberts et al. 1969; Elble and Koller 1990; Nini et al. 1995; Llinas et al. 1999; Milton and Jung 2003; Smirnov et al. 2008; Roberts et al. 2010). For example, parkinsonian resting tremor appears to be caused by a pacemaker-like population of neurons which fires in a synchronized and periodic manner (Alberts et al. 1969; Smirnov et al. 2008). In contrast, under healthy conditions,

these neurons fire in an uncorrelated, i.e., desynchronized manner (Nini et al. 1995). Permanent deep brain stimulation (DBS) at high frequencies (>100 Hz) is the standard therapy for medically refractory PD and essential tremor (Benabid et al. 1991, 2002; Blond et al. 1992). High-frequency (HF) DBS has been developed empirically, mainly based on experimental results, clinical observations, and animal experiments (Bergman et al. 1990). DBS was approved by the Food and Drug Administration (FDA) as a treatment for essential tremor in 1997, for Parkinson's disease in 2002, and for dystonia in 2003. The treatment of severe neurological and psychiatric diseases with DBS is a rapidly growing and promising field. However, in spite of many beneficial effects, in some patients, DBS may not help or may cause side effects, or the therapeutic effects may disappear over time (Tasker 1998; Volkmann 2004; Rodriguez-Oroz et al. 2005; Deuschl et al. 2006).

With the objective of finding more effective stimulation techniques with less side effects, a model-based development of novel stimulation methods has been initiated (Tass 1999, 2002a, b, 2003b; Rosenblum and Pikovsky 2004a; Hauptmann et al. 2005b; Popovych et al. 2005, 2006a; Tass et al. 2006; Hauptmann et al. 2007c; Tukhlina et al. 2007; Popovych and Tass 2010). In these studies, relevant neuronal target populations were modeled mathematically, and stimulation techniques have been developed utilizing principles from nonlinear dynamics and statistical physics (Tass 1999). One goal of this approach is to control the pathological neural dynamics appropriately in order to achieve a mild and efficient relief of symptoms (Tass 1999). The second, more ambitious goal is to stimulate in a way that the formerly affected neuronal populations unlearn their pathological connectivity and, hence, their tendency to produce pathological synchronization (Tass and Majtanik 2006). Put otherwise, the very goal of this approach is to induce long-lasting therapeutic effects which outlast the cessation of stimulation. To this end, stimulation algorithms have been developed and optimized to exploit dynamic self-organization principles and plasticity rules (Tass and Majtanik 2006; Tass and Hauptmann 2006, 2007, 2009; Hauptmann and Tass

2007, 2009, 2010; Tass and Popovych 2012; Popovych and Tass 2012).

Several novel stimulation techniques have computationally been developed in the past. In this entry, four of these control methods will be presented in detail: coordinated reset (CR) stimulation (Tass 2003a, b), multisite linear delayed feedback (MLDF) stimulation (Hauptmann et al. 2005a, b, c, 2007a, b), nonlinear delayed feedback (NDF) stimulation (Popovych et al. 2005, 2006a, b, 2008; Popovych and Tass 2010), and proportional-integro-differential feedback (PIDF) stimulation (Pyragas et al. 2007). These techniques have the common objective of reducing the extent of synchronization of the target population by reestablishing a normal desynchronized physiological activity in a formerly highly synchronized population of neurons. For other stimulation methods, we refer to Rosenblum and Pikovsky (2004a), Tukhlina et al. (2007), Kiss et al. (2007), Luo et al. (2009), Danzl et al. (2009), and Nabi and Moehlis (2011).

CR stimulation, in its original realization, uses short electrical pulse trains to subsequently reset subpopulations of the neuronal network, which induces a desynchronized state (Tass 2003a, b). The stimulation is applied through a small number of stimulation sites which are equally spaced within the neuronal population. Desynchronization is achieved by utilizing self-organization principles, in particular, the slaving principle induced by the pathological neuronal interactions (i.e., interactions which have the potential to induce a pathological synchronization) (Tass 2003a, b). Several studies addressed the optimal parameter calibration of CR stimulation (Lysyansky et al. 2011a, 2013; Lücken et al. 2013) and also suggested CR stimulation for activation of inactive or hypoactive neuronal population by multi-frequency and phase-shifted activation of the stimulated neuronal networks (Lysyansky et al. 2011b).

MLDF (Hauptmann et al. 2005a, b, c, 2007a, b) and NDF (Popovych et al. 2005, 2006a, b, 2008; Popovych and Tass 2010) stimulation use delayed feedback for stabilizing a desynchronized state which is intended to be as close to the physiological mode of action as possible. Here, the local field potential (LFP) of the target population is

measured, amplified, delayed, and fed back into the ensemble. The PIDF (Pyragas et al. 2007) utilizes an instantaneous LFP and is designed for a particularly difficult situation characterized by a separate registration and stimulation setup.

It has been shown experimentally that synaptic plasticity enhances neuronal synchronization (Nowotny et al. 2003). From the kindling phenomenon in the context of epilepsy, it is well known that neural networks may learn pathological strong interactions (Speckmann and Elger 1991; Morimoto et al. 2004). The novel desynchronizing stimulation protocols are designed to invert this pathological process, so that the affected neuronal populations unlearn their pathological connectivity, and physiological neuronal activity is reestablished on a long-term basis (Tass and Majtanik 2006; Hauptmann and Tass 2007, 2009, 2010; Tass and Hauptmann 2007; Tass and Popovych 2012; Popovych and Tass 2012). In a nutshell, the novel stimulation techniques aim at a well-directed employment of fundamental principles of dynamic brain action to induce long-lasting therapeutic effects.

Standard High-Frequency Stimulation

For high-frequency (HF) deep brain stimulation (DBS), the golden standard for the therapy of medically refractory movement disorders, depth electrodes are chronically implanted in the thalamic ventralis intermedius nucleus or the subthalamic nucleus (STN) (Benabid et al. 1991, 2002), and permanent HF (>100 Hz) periodic electrical pulse-train stimulation is applied. HF DBS has been developed empirically, mainly based on intraoperative observations, and, as yet, the mechanism of HF DBS is not sufficiently understood (McIntyre et al. 2004b). HF DBS strongly alters the neuronal firing and mimics the effect of tissue lesioning, e.g., by suppressing neuronal firing, which, in turn, suppresses the symptoms (Benabid et al. 2002; Filali et al. 2004; McIntyre et al. 2004b; Volkmann 2004). However, HF DBS is a reversible technique and has a much lower rate of side effects than lesioning with thermocoagulation (Schuurman et al. 2000).

HF DBS seems to induce a regular bursting in STN neurons during stimulation and a transient suppression of the neuronal activity mediated by a synaptic-independent blockade of the intrinsic voltage-gated currents after its cessation (Beurrier et al. 2001, 2002). Another hypothesis is that HF DBS appears to block neuronal activity in relevant target areas during stimulation (Benabid et al. 2002). In single-compartment conductance-based biophysical models of isolated STN neurons, the HF stimulation may cause a suppression of neuronal activity on an elementary membrane level, where a neuron's resting state or low-amplitude subthreshold oscillations can get stabilized (Pyragas et al. 2013). The obtained theoretical results resemble the clinically observed relations between stimulation amplitude and stimulation frequency required to suppress parkinsonian tremor (Benabid et al. 1991). Several contributing mechanisms resulting in the observed effects of HF DBS might be membrane inhibition, jamming, excitation of excitatory and inhibitory afferents, excitation of efferents, and plasticity (Benabid et al. 2005). In particular, HF stimulation of afferent axons projecting to STN can account for a therapeutic effect of HF DBS within STN (Gradinaru et al. 2009).

To precisely evaluate the contribution of these different mechanisms, spatially extended multi-compartment neuron models were used to demonstrate the effects of extracellular stimulation on the different structures of the stimulated neuronal population (Grill and McIntyre 2001). Depending on the stimulation amplitude and the shape of the stimulation pulses, either the cells were activated directly or fibers mediating excitatory or strong inhibitory action were activated (Grill and McIntyre 2001). Modeling studies indicate that already at the level of single neurons, the activation of a larger number of structures can take place with different and possibly conflicting impacts on the single neuron dynamics (Grill and McIntyre 2001).

Experimental and modeling studies also reveal that the globus pallidum interior (GPi) – one structure of the basal ganglia – might strongly be involved in the mechanisms of DBS (Hashimoto et al. 2003; Rubin and Terman 2004; Miocinovic

et al. 2006). HF stimulation of the STN regularizes GPi firing (Hashimoto et al. 2003), and this restores the responsiveness of the thalamus (Rubin and Terman 2004). Accordingly, one may distinguish between local and nonlocal effects of HF stimulation. Locally, in the vicinity of the stimulation electrode, axons rather than cell bodies (somas) get activated (McIntyre et al. 2004a), while the latter can even be effectively inhibited by HF stimulation (Benabid et al. 2002; Welter et al. 2004; Meissner et al. 2005). The stimulation-induced axonal activity propagates antidromically and orthodromically (Hammond et al. 2008) and can change the firing in the output structures downstream to the neuronal target population. The pathological discharge patterns in the target population can be replaced by HF spiking or suppressed depending on whether the efferent fibers of the stimulated nucleus are excitatory or inhibitory, respectively (Hashimoto et al. 2003; Anderson et al. 2003; McIntyre et al. 2004b). In other words, local and nonlocal effects of HF DBS may differ considerably.

HF DBS, although being clinically beneficial and widely used, still has a number of limitations. On the one hand, HF DBS may cause adverse effects like dysarthria, dysesthesia, cerebellar ataxia, and memory decline (Volkman 2004; Rodriguez-Oroz et al. 2005; Freund 2005). On the other hand, HF DBS may be ineffective, or its therapeutic effect may wear off over time (Kumar et al. 2003; Rodriguez-Oroz et al. 2005). For instance, 11–15 % of PD patients have unsatisfactory outcomes although their depth electrodes are properly placed (Limousin et al. 1999). This initiated the development of new stimulation algorithms with an extensive use of mathematical models and methods from nonlinear dynamics and statistical physics (Tass 1999).

Coordinated Reset Stimulation

Coordinated reset (CR) stimulation was designed to specifically counteract pathological synchrony by desynchronization (Tass 2003a, b). The idea behind CR stimulation (Tass 2003a, b) is to robustly shift the stimulated population into a

dynamical state which is not the desired desynchronized state, but sufficiently close to it. Close in the sense that due to the pathologically strong coupling, the population automatically relaxes into the desired desynchronized state. The scheme of the stimulation setup is presented in Fig. 1a. Several stimulation sites are placed within the target network, and weak resetting stimulation signals are administered via these

stimulation sites. In this way the oscillatory population is divided into several subpopulations, where each of them is assigned to the corresponding stimulation site and receives the stimulation signal mostly from that stimulation site. CR stimulation means that a synchronized population of neurons is stimulated with a sequence of brief resetting stimuli (typically brief HF stimulus trains; see Fig. 1b) via the

Computational Model-Based Development of Novel Stimulation Algorithms,

Fig. 1 Stimulation setup of CR stimulation method. (a) Brief and mild resetting stimuli are administered at different sites at subsequent times and effectively divide the stimulated population into several, say four, subpopulations. (b) Stimulation signals of CR stimulation in the form of short charge-balanced pulse trains. (c–f) Snapshots of the phase distribution density histograms before, during, and after (poststimulation desynchronizing transient) CR stimulation and during resynchronization as indicated in the plots. In (d), the phases ψ_j of the stimulation neurons form four phase clusters equidistantly (or close to that) distributed over the period of oscillations. In (e), a nearly uniform distribution of the oscillator phases is formed during the poststimulation transient. Plots (c–f) are adapted from Lysyansky et al. (2013)

different sites. The delay between the subsequent resetting stimuli can be chosen as $\tau = T/n$ with respect to that at the preceding site (Fig. 1a), where n is the number of stimulation sites, and T approximates the mean period of the collective dynamics of synchronized oscillators (Tass 2003a, b).

The subsequent reset of the different subpopulations induces a so-called cluster state, i.e., the whole population divided into n subpopulations which differ with respect to their mean phase. This effect is illustrated in Fig. 1d where a snapshot of the distribution of the phases ψ_j of the stimulated oscillators is shown. The phases of the population of oscillators stimulated via, e.g., four sites form four phase clusters equidistantly (or close to that) distributed over the oscillation period. To estimate the extent and type of synchronization of the whole population of N oscillators, the cluster variables

$$Z_m(t) = R_m(t)e^{i\psi_m(t)} = \frac{1}{N} \sum_{j=1}^N e^{im\psi_j(t)}, \quad (1)$$

can be used. $R_m(t)$ and $\Psi_m(t)$ are the corresponding real amplitude and real mean phase, where $0 \leq R_m(t) \leq 1$ for all time t (Daido 1992; Tass 1999). Cluster variables are convenient for characterizing synchronized states of different types: Perfect in-phase synchronization corresponds to $R_1 = 1$, whereas an incoherent state, with uniformly distributed phases, is associated with $R_m = 0$, $m = 1, 2, 3, \dots$. Small values of R_1 combined with large values of R_m are indicative of an m -cluster state consisting of m distinct and equally spaced clusters, where all oscillators within the same cluster have similar phases. In Fig. 1c–d, for instance, the variables R_1 and R_4 approximately attain the following values, respectively: (c) 0.98 and 0.72, synchronization; (d) 0.07 and 0.55, stimulation-induced four-cluster state; (e) 0.17 and 0.08, poststimulation desynchronization transient; and (f) 0.75 and 0.2, resynchronization.

From the cluster state, the neurons typically relax to a uniformly desynchronized state (Fig. 1e) before they revert back to the in-phase synchronized state (Fig. 1f), if left unperturbed. To understand how a stimulus-induced clustering leads to an effective desynchronization, the

dynamics of the leading modes $Z_1, Z_2, \dots$, can be considered. When the coupling among oscillators becomes sufficiently large, e.g., it exceeds a certain critical value, Z_1 from Eq. 1 becomes an order parameter (Kuramoto 1984), which according to the slaving principle (Haken 1983) governs the dynamics of the other, stable modes Z_m ($m = 2, 3, \dots$) on the center manifold (Pliss 1964): The order parameter Z_1 acts on a slow timescale, whereas the stable modes Z_m act on a fast timescale and relax to values given by the order parameter Z_1 (Wunderlin and Haken 1975; Haken 1983). In a system with large number of oscillators, this relationship reads (Tass 1999):

$$R_m \propto R_1^\nu \text{ with } \nu \geq 2, \quad m = 2, 3, 4, \dots \quad (2)$$

Small values of R_1 in the stimulation-induced cluster state lead to small values of other order parameters and to onset of desynchronization during the poststimulation transient. Stimulation-free neurons will eventually resynchronize if left unperturbed for sufficiently long time (Fig. 1f). Hence, to maintain a desynchronized neuronal firing, CR stimuli have to be administered repetitively.

CR stimulation exploits transient responses which are due to the oscillators' (pathologically strong) interactions. The general stimulation protocol of the intermittent CR stimulation (Tass et al. 2009; Lysyansky et al. 2011a) is illustrated in Fig. 2. Here, the collective dynamics is visualized by considering the collective firing of the neurons. A single firing/bursting model neuron fires/bursts whenever its phase is close to zero (modulo 2π) (Kuramoto 1984; Ermentrout and Kopell 1991; Grannan et al. 1993; Hansel et al. 1993; Tass 1999). The collective firing can be illustrated with the *relative number of neurons producing an action potential or burst at time t* given by

$$n_{\text{fire}}(t) = \frac{\text{number of neurons with } \cos \psi_j > 0.99}{N}. \quad (3)$$

$0 \leq n_{\text{fire}}(t) \leq 1$ for all t . $n_{\text{fire}}(t) = 0$ means that no neuron fires/bursts, while all neurons fire/burst at time t if $n_{\text{fire}}(t) = 1$. Varying the threshold

parameter 0.99 in a reasonable range does not change the results.

As shown in Fig. 2, stimulation starts when the neurons are synchronized, and the collective firing demonstrates high-amplitude rhythmic oscillations (upper-right insert in Figs. 2 and 1c). After a few periods of stimulation (Fig. 1b), the oscillatory population is shifted into a cluster state (bottom-right insert in Figs. 2 and 1d). Then the stimulation is switched off (Fig. 1b) and the ensemble returns to a synchronized state on this way passing through a uniformly desynchronized state (bottom-left insert in Figs. 2 and 1e, f). And the procedure is repeated (Fig. 1b) such that the ensemble is kept in a transient desynchronized state. The relaxation to a clustered state is due to the system being attracted by the center manifold as characterized by Eq. 2. By imposing a cluster state, the stimulation does only half of the

desynchronizing work. The rest, namely, approaching a uniformly desynchronized state, is done by the system itself. In this way, the coupling, which causes the synchronization, is used for improving the desynchronizing effect. In summary, by shifting the system into an unstable cluster state, the system reacts by automatically running through a transient desynchronized state.

The effectively desynchronizing intermittent CR stimulation (Fig. 1b) can be used to prevent from resynchronization. For this, the repetitive stimulus administration can be organized either regardless of the state of the stimulated ensemble (open-loop control) or in a demand-controlled way (closed-loop control), where the following three different control strategies can be utilized:

- (i) *Periodic administration of CR stimuli*: The most simple, open-loop type of stimulation is

Computational Model-Based Development of Novel Stimulation Algorithms, Fig. 2 A general scheme of the intermittent CR stimulation. Desynchronized firing of

neurons is maintained by repetitive administration of CR stimuli intermingled with epochs of no stimulation

a periodic administration of CR stimuli. Here, the time intervals of fixed length of CR stimulation (ON cycles) are typically recurrently followed by time intervals of fixed length where the stimulation is switched off (OFF cycles) (Fig. 1b).

- (ii) *Demand-controlled timing of the administration of identical stimuli*: Whenever the population tends to resynchronize, the same stimulus is administered (Fig. 3). The stronger the synchronization among the neurons is, the more often a stimulus has to be administered to maintain an uncorrelated firing. In an experimental application, ideally, one has to observe the synchronized oscillation during a sufficiently long period of time in order to perform a frequency analysis which yields the period T of the population in the absence of stimulation and, thus, the critical stimulation parameter τ (the time delay between successive HF pulse trains administered via different stimulation sites; see Fig. 1). Alternatively, one can also choose T according to

the known frequency range of the pathological oscillation.

- (iii) *Periodically administered HF pulse trains of demand-controlled length*: The stimuli are periodically administered with offset times $t_k = kvT$, where $k = 0, 1, 2, 3, \dots$ is the index labeling the different stimuli, $T = \bar{T} + \varepsilon$ is a time interval in the range of the period $\bar{T}$ of the population without stimulation, and v is a small integer such as 2 or 3. This means that a 1: v entrainment of the four subpopulations is performed, where the spontaneous frequency of the neurons is approximately v times larger compared to the frequency of stimulus administration. The smaller the $|\varepsilon|$, the smaller is the stimulation strength necessary to achieve an entrainment.

The closed-loop variants (ii) and (iii) require that the ensembles activity can be measured appropriately. Here, either the start times of identical CR stimuli or the length of periodically administered stimuli is calculated from the values

Computational Model-Based Development of Novel Stimulation Algorithms, Fig. 3 Desynchronizing effect of the demand-controlled intermittent CR stimulation. Time course of R_I from Eq. 1 (a, c) and of n_{fire} from Eq. 3 (b, d) during different types of stimulation. Demand-controlled timing of stimulus administration (a,

b): As soon as the amplitude R_I of the recovering order parameter reaches the value of 0.5, the stimulus is administered again. Periodic stimulation with demand-controlled length of HF pulse train (c, d): The stimulus is administered periodically, where the length of the HF pulse trains is adapted to R_I (First published in Tass (2003b))

of R_1 . For example, in the case (ii), the stimulation is started if R_1 becomes larger than a certain threshold (Fig. 3, upper two plots), whereas in the case (iii), the stimulation period is longer for larger values of R_1 measured at the onset of the stimulation (Fig. 3, bottom two plots); see references (Tass 2003a, b) for details.

Applying the standard, permanent HF stimulation (Benabid et al. 1991; Blond et al. 1992) (in a first approximation) corresponds to stimulating each neuron with the same HF pulse train. During a permanent HF stimulation, a high-frequency entrainment of the order parameter Z_1 captures Z_1 in a small portion of the complex plane (Tass 2001), so that the individual neurons' firing is stopped, but no desynchronization occurs (see also Pyragas et al. (2013)). In contrast, during stimulation, R_1 can be even larger compared to its pre-stimulus level, and after stimulation, the synchronous firing continues immediately. To suppress the firing with such a simple pulse train persistently, it has to be administered permanently. The number of single pulses used to suppress the firing in the case of the standard permanent HF pulse-train stimulation is about five and eight times larger than that used for blocking the resynchronization in Fig. 3a, b and 3c, d, respectively. This illustrates the effectiveness of the demand-controlled CR stimulation. The latter can effectively desynchronize stimulated oscillators with a significantly smaller amount of stimulation current compared to the standard permanent HF pulse-train stimulation.

The efficacy of CR stimulation can further be improved by an optimal choice of the stimulation parameters. Several computational studies on neuronal models of different complexity have addressed this problem and showed that intermittent $m:n$ ON-OFF CR stimulation, where m cycles with stimulation ON are recurrently followed by n cycles with stimulation OFF, is most effective for a weak stimulation intensity and short ON intervals (Lysyansky et al. 2011a). The stimulation-induced cluster state leads to the longest desynchronized poststimulation transient which can further be prolonged for nonuniform timing of the stimuli onsets (Lücken et al. 2013). The number of stimulation sites is another important

stimulation parameter, and its optimal choice essentially depends on the properties of the neuronal tissue (Lysyansky et al. 2013). For a weak (strong) spatial decay rate of the stimulation current with distance to the stimulation site, CR stimulation can optimally be delivered via small (large) number of stimulation sites.

Spike Timing-Dependent Plasticity

It is well known that synapses in the brain are involved in the adaptation process, where their efficacy is governed by spike timing-dependent plasticity (STDP) (Gerstner et al. 1996; Markram et al. 1997; Feldman 2000; Wittenberg and Wang 2006; Caporale and Dan 2008). Plasticity is a fundamental property of the nervous system: In order to learn and to adapt to sensory inputs, neurons continuously regulate the strength of their synaptic connections in relation to the mutual timing properties of their firing or bursting (Hebb 1949; Gerstner et al. 1996; Markram et al. 1997; Debanne et al. 1998; Kilgard and Merzenich 1998; Abbott and Nelson 2000; Feldman 2000; Song et al. 2000; van Hemmen 2001; Zhou et al. 2003). However, plasticity may not only lead to desired learning and optimization processes. Rather neuronal populations can learn pathologically strong interactions which may lead, e.g., to the emergence of epilepsy (Morimoto et al. 2004; Speckmann and Elger 1991). This is well known from the so-called kindling phenomenon (Goddard 1967), where preparatory stimulation induces the spontaneous production of epileptic seizures without gross morphological changes (Morimoto et al. 2004).

An example of the STDP function is illustrated in Fig. 4a (see also references Bi and Poo (1998) and Bi (2002)), and the synaptic weights are updated in a point-like process by the increment $W(\Delta t)$ as soon as the pre- and postsynaptic neurons fire. For such a plasticity rule, the synaptic weight is potentiated or depressed depending on whether the postsynaptic firing follows or advances the presynaptic firing, respectively. STDP can lead to multistability where states with different connectivity and different collective dynamics may

coexist. If, for instance, the initial coupling is weak, the neurons get desynchronized, and the spiking time differences Δt get broadly (e.g., uniformly) distributed. Then STDP (Fig. 4a) leads to further suppression of the coupling (see Fig. 4b for large ε where $\overline{\Delta k} < 0$), the neurons remain desynchronized, and a weakly coupled desynchronized state stabilizes. On the other hand, if the initial coupling is strong, the neurons fire synchronously, i.e., the spiking time differences are narrowly distributed around zero (see Fig. 4b for small ε where $\overline{\Delta k} > 0$), and synaptic weights get further potentiated. Such initial conditions result in a strongly coupled synchronized state. Along with the two regimes mentioned above, some other states with intermediate coupling strength and synchronization may coexist as well.

The impact of plasticity on synaptic weights and collective neural dynamics has been accounted for by several theoretical studies on desynchronizing stimulation methods (Tass and Majtanik 2006; Hauptmann and Tass 2007; Tass and Hauptmann 2007). They have initiated an approach which is targeted on unlearning pathologically strong synaptic interactions by desynchronizing brain

stimulation and which has further been developed in subsequent papers (Hauptmann and Tass 2009, 2010; Tass and Popovych 2012; Popovych and Tass 2012). This approach exploits plasticity in two different ways: On the one hand, due to plasticity, desynchronizing stimulation may decrease the strength of the neurons' synapses by decreasing the rate of coincidences. On the other hand, neuronal networks with synaptic plasticity may exhibit bi- or multistability (Seliger et al. 2002; Tass and Majtanik 2006; Hauptmann and Tass 2007; Tass and Hauptmann 2007; Maistrenko et al. 2007). Accordingly, by decreasing the mean synaptic weight, desynchronizing stimulation may shift a neuronal population from a stable synchronized (pathological) state to a stable desynchronized (healthy) state, where the neuronal population remains thereafter, if left unperturbed.

In PD neuronal populations of the basal ganglia are strongly synchronized (Beurrier et al. 2002; Schnitzler et al. 2006; Timmermann et al. 2007). By the same token, abnormal neural synchrony is a hallmark of tinnitus (Llinas et al. 1999; Weisz et al. 2005; Roberts et al. 2010; Adamchic et al. 2013). In the synchronized regime, synaptic plasticity results in a further amplification of the synchronized activity by a strengthening of the synaptic connections (Nowotny et al. 2003). Properly designed stimulation may be used to break this vicious circle and to induce an anti-kindling (Tass and Majtanik 2006; Hauptmann and Tass 2007, 2009, 2010; Tass and Hauptmann 2007; Tass and Popovych 2012; Popovych and Tass 2012), which finally may reestablish the normal level of connectivity, associated with a mostly uncorrelated neuronal activity. In this way a sustained long-lasting desynchronization can be achieved, and therapeutic aftereffects can be established after the cessation of desynchronizing stimulation as predicted computationally (Tass et al. 2012a, b).

The anti-kindling process in neural networks with STDP is illustrated in Fig. 5 for CR stimulation for two stimulation modalities: somatic electrical and synaptically mediated (e.g., sensory) stimulation, which were suggested for desynchronizing electrical DBS (Tass 2003a, b; Tass and Majtanik 2006) and for the treatment of

Computational Model-Based Development of Novel Stimulation Algorithms, Fig. 4 (a) Normalized plasticity function versus the difference of the spike/burst timing of post- and presynaptic neuron $\Delta t = t_{\text{post}} - t_{\text{pre}}$. (b) The average update rate of synaptic weights $\overline{\Delta k} \varepsilon = W(\xi)\rho(\xi)d(\xi)$ for the uniform distribution density $\rho = 1/2 \varepsilon$ of $\Delta t \in [-\varepsilon, \varepsilon]$

Computational Model-Based Development of Novel Stimulation Algorithms, Fig. 5 Stimulation-induced rewiring and desynchronization of the neural ensemble with STDP by desynchronizing coordinated (CR) stimulation. The time courses of the mean synaptic weights $\bar{c}(t)$ are plotted for different stimulation intensities I as indicated in the legends. The stimulation time interval is

indicated by the red bar and by the vertical dashed lines for direct electrical CR stimulation, indirect excitatory CR stimulation, and indirect inhibitory CR stimulation (as indicated in the plots) delivered to a neuronal population in a strongly coupled and synchronized regime; see (Popovych and Tass 2012) for details (Adapted from Popovych and Tass (2012))

tinnitus by noninvasive acoustic stimulation (Tass and Popovych 2012), respectively. For both stimulation modalities, there exist a range of stimulation intensities, where CR stimulation can effectively change the collective dynamics of the stimulated neural network to a weakly coupled and desynchronized regime which stably persists after the stimulation is completely switched off (Fig. 5, green curves; Popovych and Tass 2012). Desynchronizing CR stimulation results in an anti-kindling of the pathological connectivity, and, finally, the physiological weakly coupled and desynchronized state is reestablished. This may lead to long-lasting therapeutic effects of CR stimulation. On the other hand, too weak or too strong CR stimulation does not cause long-lasting effects, and the synaptic connectivity returns to the pre-stimulation level after cessation of stimulation (Fig. 5, blue and red curves, respectively). In the latter case, however, CR stimulation

may induce an acute (during stimulation) normalization of abnormal connectivity.

The theoretical findings on the properties of CR stimulation have been verified experimentally. The resetting impact and the induced transient desynchronization of an electrical short-pulse stimulation, on which the CR technique is based, have been reported *in vivo* for coupled neuronal bursters in paddlefish (Neiman et al. 2007). Taking into account STDP, the long-lasting desynchronizing effects of CR stimulation have been investigated in detail in theoretical studies (Tass and Majtanik 2006; Tass and Hauptmann 2007; Hauptmann and Tass 2007), and the results have been confirmed experimentally *in vitro* in rat hippocampal slice (Tass et al. 2009). The beneficial therapeutic long-lasting aftereffects of the weak electrical CR stimulation have been observed in the MPTP-treated macaque monkeys, in contrast to a stronger CR stimulation and to

standard HF DBS (Tass et al. 2012b). It was shown that unilateral CR stimulation delivered to the STN of parkinsonian MPTP monkeys for only 2 h per day during 5 days leads to significant and sustained therapeutic aftereffects for at least 30 days, while standard 130 Hz DBS and strong CR stimulation have no aftereffects (Tass et al. 2012b).

Computational studies revealed that CR stimulation is effective for a number of stimulation setups and demonstrates a great applicability. CR stimulation has been suggested for counteraction of a cerebral hypoactivity found in a number of diseases (Candy et al. 1983; Wolkin et al. 1992; Salehi et al. 1994; Kishimoto et al. 1998; Bearden et al. 2001), without promoting pathological synchronization, by a multifrequency and phase-shifted activation of the stimulated neuronal networks (Lysyansky et al. 2011b). Other computational studies showed that CR stimulation can be effective in inducing desynchronization for direct somatic stimulation and as well as for excitatory or inhibitory synaptically mediated stimulation (Popovych and Tass 2012); see Fig. 5. The latter stimulation setup might correspond to stimulation of afferent or efferent fibers or sensory stimulation where the stimulation signals arrive at the neural target population as postsynaptic potentials. Sensory CR stimulation has been suggested for desynchronizing the neural synchrony underlying tinnitus (Tass and Popovych 2012) and successfully verified in a clinical proof of concept study in tinnitus patients treated with noninvasive acoustic CR stimulation (Tass et al. 2012a; Silchenko et al. 2013; Adamchic et al. 2013). It turned out that acoustic CR stimulation can significantly counteract both tinnitus symptoms and the underlying pathological neuronal synchronization by normalizing the effective connectivity and restoring the functional patterns of activity (Tass et al. 2012a; Silchenko et al. 2013; Adamchic et al. 2013).

Multisite Linear Delayed Feedback

Similarly as in the case of CR stimulation, multisite linear delayed feedback (MLDF) (Hauptmann

et al. 2005a, b, c, 2007a, b) is administered via several stimulation sites, e.g., via four sites as illustrated in Fig. 1a. The individual stimulation signals $S_m(t)$ of each of the stimulation sites are however derived from the delayed mean field $Z(t)$ of the stimulated ensemble using different time delays for different stimulation signals. The mean field characterizes the collective macroscopic dynamics of the oscillators and can be viewed as the ensemble average of the signals $z_j(t)$, $j = 1, \dots, N$, of individual oscillators, $z(t) = N^{-1} \sum_{j=1}^N z_j(t)$.

For n stimulation sites, the stimulation signals are calculated as $S_m(t) = KZ(t - \tau_m)$, $m = 1, \dots, n$, where K is the amplification parameter, and the values of delay τ_m , for example, for $n = 4$ are calculated from the following relation

$$\tau_m = \frac{11 - 2(m - 1)}{8} \tau, \quad m = 1, 2, 3, 4 \quad (4)$$

The delays τ_m are symmetrically distributed with respect to the main delay τ , where the smallest time delay between neighboring stimulation sites is chosen as $\tau/4$. In the case $\tau = T$ (mean period of the ensemble), the delays τ_m are uniformly distributed over the mean period T . In another realization, instead of four delays τ_m , $m = 1, \dots, 4$, one can use only two of them, e.g., τ_1 and τ_2 . One can put $\tau_3 = \tau_1$ and $\tau_4 = \tau_2$, where the polarity of the stimulation signals $S_3(t)$ and $S_4(t)$ is reversed: $S_3(t) = -S_1(t)$ and $S_4(t) = -S_2(t)$. Assuming that the mean field of the ensemble uniformly oscillates with period $T = \tau$, the alternating polarity of the signal corresponds to a shift in time by half a period. Therefore, under this condition, the stimulation signal $S_3(t) = -S_1(t) = -KZ(t - \tau_1)$ approximates the stimulation signal $S_1(t + \tau/2)$ which is shifted in time by half of the period, which, in turn, is equal to $KZ(t - \tau_3)$, where τ_3 is calculated according to Eq. 4. Analogous arguments are applicable to the stimulation signal $S_4(t) = -S_2(t) = -KZ(t - \tau_2)$.

If the phase $\Psi(t)$ of the mean field $Z(t)$ (see also Z_I from Eq. 1) uniformly rotates with a constant frequency $\Omega = 2\pi/\tau$, the phases $\Phi_m(t) = \Psi(t - \tau_m)$ of the stimulation signals $S_m(t)$ are equidistantly distributed over the unit circle as illustrated in Fig. 6a. Then the phases $\psi_j(t)$ of the stimulated

In the subplots, four trajectories from each of the four stimulated subpopulations assigned to each of the four different stimulation sites are shown for $t \in (320, 340)$. Parameter $\tau = T$ in **(b)** and $\tau = 2T$ in **(c)**

neuronal subpopulation assigned to the stimulation site m are attracted to the phase $\Psi(t - \tau_m)$ of the corresponding stimulation signal. Hence, the phases of all oscillators stimulated with MLDF become symmetrically redistributed on the circle $(0, 2\pi)$ in a cluster state. The order parameter $R_1(t)$ is thus minimized. Depending on the value of the delay τ , the stimulation can induce different cluster states in the stimulated ensemble, where the corresponding order parameter R_m attains large values.

As shown in Fig. 6b, c, the in-phase synchronization in the stimulated ensemble is effectively suppressed (for time $t > 200$, where both coupling and stimulation are switched on), where the order parameter $R_1(t) = |Z_1(t)|$ from Eq. 1 attains small values (Fig. 6b, c, red curve). This indicates a symmetrical redistribution of the oscillator phases $\psi_j(t)$ over the unit circle. For the parameter τ close

to the mean period T of the stimulation-free ensemble, a four-cluster state is induced by the stimulation, where the order parameters R_1 and R_2 are small, whereas R_4 is relatively large (Fig. 6b). In the inset showing four trajectories from each of the stimulated subpopulations, the emerging four-cluster state induced by MLDF is illustrated. For τ closer to, for example, $2T$, the stimulation induces a two-cluster state, where R_1 is small, whereas R_2 and R_4 are large (Fig. 6c). The oscillators thus split into two clusters, which is also illustrated in the inset in Fig. 6c.

MLDF robustly suppresses in-phase synchronization as shown in Fig. 7a, where the time-averaged order parameter $\langle R_1 \rangle$ attains small values for a broad range of parameters τ and K . On the other hand, depending on system and stimulation parameters, MLDF can induce either a two-cluster state, where the second order

Computational Model-Based Development of Novel Stimulation Algorithms, Fig. 7 Impact of the MLDF stimulation versus parameters τ and stimulus amplification K . The time-averaged order parameters $\langle R_1 \rangle$, $\langle R_2 \rangle$ and $\langle R_4 \rangle$ are depicted in plots (a–c), respectively, and encoded in color ranging from 0 (blue) to 1 (red). In plot (d), the

impact of the single-site linear delayed feedback (SLDF) on the oscillatory population is illustrated, where the values of the order parameter $\langle R_1 \rangle$ are depicted in color versus parameters τ and K (First published in Popovych et al. (2006a,b))

parameter R_2 attains relatively large values (e.g., for $\tau \approx 2T$; see Fig. 7b), or a four-cluster state, where R_2 becomes small and the fourth order parameter R_4 increases (e.g., for $\tau \approx T$; see Fig. 7c). Therefore, the whole stimulated population splits into two or four distinct subpopulations. Within the phase clusters, the individual oscillators have phases close to each other, while the different phase clusters are equidistantly distributed on the circle. Hence, depending on the values of the parameters τ and K , MLDF with four stimulation sites may cause either a two-cluster state, where R_1 is close to zero and R_2 is large, or a four-cluster state, where both R_1 and R_2 are small, but R_4 is large. The cluster states become less pronounced, and the phases redistribute on the circle even more uniformly if a local coupling as well as a spatially decaying profile of the current spread is taken into account (Hauptmann et al. 2005a).

In Fig. 7d a similar two-parameter diagram for the averaged order parameter $\langle R_1(t) \rangle$ is presented for a single-site linear delayed feedback (SLDF) suggested for synchronization control in references (Rosenblum and Pikovsky 2004a, b). The stimulation is performed via one stimulation electrode in such a way that all oscillators of the ensemble (in a first approximation) receive the same stimulation signal $S(t)$. In this case the stimulation signal $S(t)$ attains the form $S(t) = KZ(t - \tau)$. For stimulation with SLDF, in the corresponding two-parameter diagram (Fig. 7d), islands of perfect desynchronization are complemented by areas of stimulation-enhanced synchronization. In the limit $N \rightarrow \infty$, the order parameter $R_1 = 0$ in the desynchronization regions, where the phases are uniformly distributed on the circle $(0, 2\pi)$ (Rosenblum and Pikovsky 2004a, b). This is the state of complete desynchronization, where the stimulated

oscillators rotate with different frequencies indicating an absence of any cluster state whatsoever. The island-like structure of desynchronization regions in parameter space of SLDF (Fig. 7d) was also experimentally confirmed for arrays of coupled electrochemical oscillators (Zhai et al. 2008).

The important property of the stimulation with the multi- and single-site linear delayed feedback is the inherit demand-controlled character of the methods. As soon as the desired desynchronized state is achieved, the values of the order parameter $R_I(t)$, i.e., the amplitude of the mean field, become small. Along with the order parameter, in the desynchronized state, the amplitude of the stimulation signal $S(t)$ vanishes as well. Stimulation with multi- and single-site linear delayed

feedback thus represents a noninvasive control method for desynchronization of coupled oscillators. The stimulated ensemble is then subjected to a highly effective control at a minimal amount of stimulation force.

Nonlinear Delayed Feedback

As in the case of the single-site linear delayed feedback, for the stimulation with nonlinear delayed feedback (NDF), only one registering and one stimulating site is required; see Fig. 8a. All stimulated oscillators receive the same stimulation signal $S(t)$ which is constructed from the measured mean field of the ensemble. It is assumed that the measured mean field $Z(t)$ of the

Computational Model-Based Development of Novel Stimulation Algorithms,

Fig. 8 Control of synchronization by nonlinear delayed feedback (NDF) stimulation. (a) The macroscopic activity (mean field) of the controlled population is measured, delayed, nonlinearly combined with the instantaneous mean field, amplified, and fed back via a single stimulation site. (b, c) Desynchronization of strongly synchronized oscillators by NDF. Time courses of the order parameter $R_I(t)$ (red curves) and the amplitude of the stimulation signal $|S(t)|$ (blue curves) are plotted for delays (b) $\tau = T/2$ and (c) $\tau = T$, where T is the mean period of the stimulation-free ensemble. In the insets, trajectories of two selected oscillators are depicted in the stimulated regime (First published in Popovych et al. (2008))

ensemble has the form of a complex analytic signal $Z(t) = X(t) + iY(t)$, where $X(t)$ and $Y(t)$ are the real and imaginary parts of $Z(t)$, respectively. If only the real part $X(t)$ of the mean field is measured, the imaginary part can be calculated, e.g., with the Hilbert transform (Pikovsky et al. 2001). The stimulation signal is then constructed by a nonlinear combination of a delayed complex conjugate mean field with the instantaneous mean field (Popovych et al. 2005, 2006a, b, 2008; Popovych and Tass 2010)

$$S(t) = KZ^2(t)Z^*(t - \tau) \quad (5)$$

where K is a stimulus amplification parameter, τ is a time delay, and the asterisk denotes complex conjugacy.

The desynchronizing effect of the stimulation with NDF is illustrated in Fig. 8b, c. NDF (with onset at $t = 550$) desynchronizes the stimulated oscillators, and the order parameter R_I reaches values of approximately the same order of magnitude as in the uncoupled regime ($t < 400$). This indicates a high level of desynchronization. The stimulation does not destroy the normal oscillatory activity of the individual oscillators. In the insets in Fig. 8b, c, individual trajectories of two selected oscillators of the stimulated ensemble are plotted. The stimulated oscillators rotate with different individual frequencies just as in the coupling- and stimulation-free regime.

As soon as a desynchronized state is achieved, the stimulation force decreases, and the stimulated system is subjected to a highly effective control with a minimal amount of stimulation force. Also, as soon as the oscillators resynchronize, the mean field starts to exhibit large-amplitude oscillations, and the stimulation signal increases in amplitude and brings the ensemble back to a desynchronized state. This demand-controlled character of the nonlinear delayed feedback is illustrated in Fig. 8c where the onsets of resynchronization (increase of $R_I(t)$, red curve) at times around $t \approx 850, 1050$, and 1200 lead to an increase of the amplitude of the stimulation signal $|S(t)|$ [blue curve], which in turn results in a suppression of the resynchronization.

The impact of the nonlinear delayed feedback on the stimulated oscillators is twofold. On the

one hand, the stimulation can effectively desynchronize even strongly interacting oscillators within a large range of values of the stimulus amplification K ; see Fig. 9a. This effect is very robust with respect to a variation of the delay τ and, as a result, with respect to a variation of the mean frequency Ω of the stimulated ensemble. On the other hand, in a weakly coupled ensemble, the stimulation can induce synchronization in island-like regions of small values of the stimulus amplification K complemented by domains of desynchronization; see Fig. 9b.

An increase of the stimulus amplification parameter K results in a gradual decay of the order parameter R_I for both strongly and weakly coupled oscillators, which indicates the onset of desynchronization in the stimulated ensemble. Simultaneously, the amplitude of the stimulation signal $|S(t)|$ decays as well, indicating the demand-controlled character of the nonlinear delayed feedback stimulation. For a fixed delay $\tau > 0$, the order parameter and the amplitude of the stimulation signal decay as $|K|$ increases according to the following power law (Fig. 9c):

$$R_I \sim |K|^{-1/2}, |S| \sim |K|^{-1/2}. \quad (6)$$

For large values of K , all stimulated oscillators rotate with different frequencies close to the natural frequencies (Popovych et al. 2005, 2006a, 2008). The oscillators thus exhibit a uniform desynchronous dynamics without any kind of cluster states. In addition, depending on the values of the delay τ , the nonlinear delayed feedback can significantly change the mean frequency Ω , i.e., the frequency of the mean field $Z(t)$ of the stimulated ensemble (Popovych et al. 2005, 2006a, 2008). The macroscopic dynamics can thus be either accelerated or slowed down, whereas the individual dynamics remains close to the original one. This enables an approach for frequency control of the oscillatory population stimulated with NDF.

Mixed Nonlinear Delayed Feedback

The NDF method can also be applied for desynchronization and decoupling of two (or more) interacting oscillator populations. For

Computational Model-Based Development of Novel Stimulation Algorithms, Fig. 9 Robustness of the NDF effects. (a) Stimulation-induced desynchronization and (b) stimulation-induced synchronization in ensembles of (a) strongly coupled and (b) weakly coupled oscillators. The time-averaged values of the order parameter $\langle R_1 \rangle$ are

encoded in color ranging from *red* (synchronization) to *blue* (desynchronization) versus delay τ and stimulus amplification K . (c) Log-log plot of the time-averaged order parameter $\langle R_1 \rangle$ and amplitude of the stimulation signal $\langle |S(t)| \rangle$ versus K . The *dashed line* has the slope -0.5 and is given for comparison

this, mixed NDF can be used (Popovych and Tass 2010), see Fig. 10a. For a drive-response coupling scheme, the coupling within population 2 is assumed to be weak, so that, being isolated from population 1, no synchronization emerges in population 2. In contrast, the coupling in population 1 is strong enough to cause synchronization within population 1. It then drives the second population, which synchronizes because of the driving and sends a response signal back to population 1. The second ensemble is stimulated with signal $S(t)$, which is constructed from the mixed mean field Z_ε according to the rule of NDF from Eq. 5. The mixed mean field $Z_\varepsilon = \varepsilon W_1 + (1 - \varepsilon)W_2$ is a linear combination of the mean fields W_1 and W_2 of populations 1 and 2, respectively.

The level of mixing of the mean fields W_1 and W_2 within the stimulation signal is given by the parameter ε . Depending on ε the mixed NDF can have different desynchronizing effects on populations 1 and 2.

- *Small ε* : Mostly population 2 contributes to the stimulation signal. The mixed NDF desynchronizes the driven and stimulated population 2 (Fig. 10c), but the driving ensemble 1 remains unaffected and exhibits strongly synchronized dynamics (Fig. 10b). The populations get effectively decoupled from each other.
- *Intermediate ε* : Both populations equally contribute to the stimulation signal. Both ensembles remain synchronized (Fig. 10b, c).
- *Large ε* : Mostly population 1 contributes to the stimulation signal. Both ensembles are effectively desynchronized by the mixed NDF (Fig. 10b, c).

In the latter case, the desynchronization induced by the mixed NDF in the driven and stimulated population 2 propagates to the drive population 1 which is not directly stimulated. This is indicative of an indirect control of synchronization by the mixed NDF.

Computational Model-Based Development of Novel Stimulation Algorithms, Fig. 10 Desynchronization and decoupling of interacting populations by the mixed NDF. (a) Stimulation setup: The measured mean fields of populations 1 and 2 are linearly combined into a mixed mean field, processed by the NDF algorithm (Eq. 5) and fed back to the target population 2. Proportional-Integro-Differential Feedback

For a particularly difficult situation, where measurement and stimulation are not possible at the same time and at the same place, there is another control method which is based on a proportional-integro-differential feedback (PIDF). The scheme of this stimulation protocol is sketched in Fig. 11a, see also Fig. 10a for $\epsilon = 1$ except for the measured signal being processed by a PIDF algorithm. The controlled ensemble of N coupled oscillators is divided into two separate subpopulations of N_1 and $N_2 = N - N_1$ oscillators, one being exclusively measured and the other being exclusively stimulated. In this way a separate stimulation-registration setup is realized, where the recording and stimulating sites are spatially separated and the measured

signal is not corrupted by stimulation artifacts. The observed signal is considered to be the mean field W_1 of the measured subpopulation. Below, the main attention will be paid to the proportional-differential (PD) feedback only (for more details, see reference Pyragas et al. 2007). Then, the stimulation signal $S(t)$ administered to the second, stimulated subpopulation is constructed as

$$S(t) = PW_1(t) + DW_1(t), \quad (7)$$

where the parameters P and D define the strength of the proportional and differential feedback, respectively.

The effect of the stimulation with PD feedback is illustrated in Fig. 11b. As the strength of the feedback (parameters P and D) increases, the stimulation results in a complete desynchronization of

the whole ensemble. The threshold of the onset of desynchronization depends on the relative splitting $N_1:N_2$ of the oscillators between subpopulations and on the mean frequency Ω : The threshold is larger for the smaller number of oscillators N_2 in the stimulated populations or for larger frequency Ω . The latter dependence can be eliminated if an integral component is included in the stimulation signal; see reference (Pyragas et al. 2007). Moreover, if the coupling in the ensemble is rather weak, the desynchronization can be achieved by applying the proportional feedback only. In contrast, in the case of strong coupling, the stimulation signal additionally requires the differential feedback for robust desynchronization. As illustrated in the two-parameter diagrams in Fig. 11c, d, there exists a certain threshold in parameters P and D values, where the stimulation with PIDF desynchronizes both subpopulations in the target ensemble: stimulated subpopulation (Fig. 11d) and also measured, non-stimulated subpopulation (Fig. 11c). In this sense, the PIDF stimulation method appears to be very effective even for a complicated stimulation protocol with a separate stimulation-registration setup.

Closed-Loop DBS

The standard setup of HF DBS utilizes an open-loop stimulation protocol where a permanent HF electrical pulse train is administered to the target nucleus (Benabid et al. 1991; Volkmann 2004). Systematic investigations of the influence of the stimulation parameters were performed with a focus on the optimization of standard HF DBS via an appropriate parameter calibration (Rizzzone et al. 2001; Moro et al. 2002; Rubin and Terman 2004) including computational approaches toward a closed-loop optimization setup (Feng et al. 2007a, b).

In monkeys rendered parkinsonian with the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a closed-loop DBS was tested under acute conditions (Rosin et al. 2011). To this end, a short train (comprising seven pulses at 130 Hz) was delivered through a pair of electrodes located in the GPi at a predetermined, fixed latency (80 ms) following each action potential

recorded through an electrode placed in the primary motor cortex (M1). This type of stimulation caused a strong decrease of the firing rate of pallidal neurons together with a pronounced decrease of the oscillatory neuronal activity at the tremor frequency (4–7 Hz) and at the double tremor frequency (9–15 Hz) along with an amelioration of the MPTP-induced akinesia. After cessation of this type of closed-loop DBS, the initial firing pattern reverted back, i.e., pallidal firing rate and pallidal oscillatory activity attained pre-stimulus levels (Rosin et al. 2011). In contrast, standard continuous 130 Hz DBS caused a less pronounced decrease of the pallidal firing rate, the oscillatory neuronal activity, and the amelioration of the akinesia (Rosin et al. 2011).

Another study (Little et al. 2013) confirmed the efficacy of the closed-loop adaptive DBS (aDBS) in PD patients, where the onsets and offsets of HF stimulation were triggered by a threshold crossing by LFP in beta band measured via the same stimulation electrode implanted in STN. The stimulation trigger threshold for the LFP amplitude was heuristically determined in such a way that a reduction of the stimulation time of approximately 50 % was achieved while maintaining clinical effect. The onset of HF stimulation was delayed by 30–40 ms after the crossing of the threshold by LFP, and the stimulation was sustained until beta amplitude fell below the threshold again (Little et al. 2013). For the same stimulation intensity and stimulation frequency (130 Hz), the aDBS can be about 30 % more effective than standard continuous HF DBS, while less than 50 % of the total electrical energy is delivered in the aDBS mode as compared to continuous HF DBS. Moreover, despite of the used fixed beta threshold, the triggered stimulation duration (per 10-s block) progressively drops over time during stimulation in the aDBS mode, which suggests that aDBS may lead to positive adaptive effects in pathological parkinsonian networks (Little et al. 2013).

Summary

High-frequency deep brain stimulation is the standard therapy for the treatment of medically

Computational Model-Based Development of Novel Stimulation Algorithms, Fig. 11 PIDF control: (a) The mean field is measured in one part of the controlled ensemble and, after processing according to proportional-integro-differential feedback (PIDF) algorithm, administered to the other part of the ensemble. (b) The time-averaged order parameter $\langle R_1 \rangle$ of the whole ensemble versus the strength of the PD feedback (with $P = D$) for different splitting N_i :

refractory movement disorders (Benabid et al. 1991; Volkmann 2004). To overcome limitations of this type of therapy, a model-based development of novel deep brain stimulation techniques has been initiated (Tass 1999). The ingredients of

this approach are dynamic neuronal self-organization principles combined with fundamental plasticity rules of the nervous system (Tass 2003a, b; Tass and Majtanik 2006; Tass and Hauptmann 2006, 2007; Hauptmann and Tass

2007, 2009, 2010; Tass and Popovych 2012; Popovych and Tass 2012).

The control methods discussed in this entry differ with respect to the stimulation setup and stimulation effects as well as other properties such as robustness and applicability. For example, CR stimulation, in an open-loop protocol, is simple to apply, does not require sophisticated calibration, and effectively causes desynchronization of the stimulated oscillators. As mentioned above, a number of computational and experimental studies confirmed the applicability and efficacy of CR stimulation under different stimulation modalities.

Other smart feedback methods are more difficult to realize conceptually and technically and await experimental proof of concept. In modeling studies, they effectively result in a sustained desynchronized regime. The feedback methods can be applied under a variety of conditions and possess an intrinsic demand-controlled character, where the stimulation signal is significantly reduced or even vanishes as soon as desynchronization is achieved. The experimental and clinical realization of these methods is a challenging task, first of all, from the technical side, since stimulation signals have to fulfill all safety aspects like charge density limits. These limits strongly affect the applicability of the slow feedback signals, i.e., slow compared to the timescales of HF and CR pulses. In this way, the application conditions of the methods have to be handled with care, and stimulation setups and effects have to clearly be distinguished for different feedback methods. Otherwise, one can come up with misleading conclusions and erroneous interpretations of the efficacy of feedback methods; see the computational study (Dovzhenok et al. 2013) where nonlinear and linear techniques were not properly distinguished. To this end, only an experimental proof can finally assess the applicability and performance of the control methods.

In forthcoming studies, the mathematical modeling needs to be refined to incorporate further anatomical and physiological details, for instance, contributions of glial cells (Silchenko and Tass 2008). By the same token, control techniques have to be optimized and further

developed. As currently done for CR stimulation, clinical studies are necessary to evaluate the therapeutic effects of the novel stimulation techniques under real conditions. This interdisciplinary endeavor might finally provide superior therapies for patients with neurological or psychiatric diseases.

Glossary

Coordinated reset stimulation Coordinated reset (CR) stimulation is an effectively desynchronizing control technique, where a population of synchronized oscillators is stimulated via several stimulation sites in such a way that spatially and timely coordinated phase reset is achieved in subpopulations assigned to each of the stimulation sites. This method is suggested for counteraction of abnormal neuronal synchronization characteristic for several neurological diseases and amelioration of their symptoms. It has successively been verified in a number of experimental and clinical studies.

Deep brain stimulation Electrical deep brain stimulation (DBS) is the standard therapy for medically refractory movement disorders, e.g., Parkinson's disease and essential tremor. It requires a surgical treatment, where depth electrodes are chronically implanted in target areas like the thalamic ventralis intermedius nucleus or the subthalamic nucleus. For standard DBS, electrical high-frequency (>100 Hz) stimulation is permanently delivered via depth electrodes. More sophisticated deep brain stimulation techniques are in the process of being established for clinical use.

Delayed feedback Delayed feedback is a method for the creation of a closed-loop forcing, where a portion of the measured output signal of a system is time delayed, linearly or nonlinearly processed, and fed back into the system. This approach is often used to control the dynamic behavior of complex systems. In this entry, delayed feedback is used to control synchronization in ensembles of coupled oscillators, e.g., neurons.

Order parameter The order parameter is a quantity characterizing a phase transition or phase change in the transformation of a complex system from one phase (state) to another. The order parameter is convenient for characterizing the onset and extent of synchronization in larger ensembles: Perfect phase synchronization corresponds to a large value of the order parameter, whereas an incoherent (desynchronized) state is associated with a small value of the order parameter. In synergistics it has been shown that the dynamics of complex systems may be governed by only a few order parameters.

Synchronization Synchronization (from Greek *syn* = the same, common and *chronos* = time) means the adjustment of rhythms of self-sustained oscillators due to their weak interaction. The interacting oscillators can be regular (periodic) or chaotic. There are several different forms of synchronization including phase, complete, generalized, and lag synchronization, etc. In this entry, we focus on phase synchronization. In the simplest form, the oscillators, rotating with the same frequency, become phase synchronized (phase locked) to each other, if the difference of their phases remains bounded, e.g., constant. In the presence of noise, phase synchronization is characterized by the presence of one or more prominent peaks of the distribution of the phase difference. Put otherwise, the oscillators adjust their rhythms, while their amplitude dynamics need not be correlated.

Computational Modeling of Olfactory Behavior

Christiane Linster¹ and Thomas A. Cleland²

¹Computational Physiology Lab, Department of Neurobiology and Behavior, Cornell University, Ithaca, NY, USA

²Computational Physiology Lab, Department of Psychology, Cornell University, Ithaca, NY, USA

Definition

Computational modeling is an essential tool for developing an understanding of how nervous systems compute. This is particularly so for questions that span levels of analysis, attempting to integrate cellular, neuromodulatory, and electrophysiological data with behavioral performance. In neuroscience, computational techniques are used to study the mechanisms underlying neuronal or network responses to simple and complex inputs, analyze interactions among the parameters governing the properties of a neuron or network, and determine the coordinated mechanisms that underlie experimentally observed rich phenomena such as coherent oscillations or synaptic plasticity. In particular, computational modeling has been successful in associating neural activity with behavioral function, proposing neurophysiological mechanisms for observed behavioral capabilities, and generating novel, testable hypotheses. In our lab, computational models of behavioral phenomena have enabled us to elucidate relationships among odorant physical properties, top-down neuromodulatory signals, olfactory neural network operations, and odor perception. We here briefly review this approach and highlight some examples from the last ten years.

Computational Modeling

- [Polypeptide and Protein Modeling for Drug Design](#)

Detailed Description

Our standard approach to modeling olfactory behavior is as follows: (1) determine via behavioral pharmacology or similar experiments which

olfactory brain areas are likely to underlie a certain aspect of olfactory perception; (2) create a computational simulation of those brain areas, incorporating as much constraining experimental detail as possible given the level of modeling chosen; (3) use the model to simulate specific relationships between neural activity patterns and perception, generating testable hypotheses; and (4) based on these hypotheses, perturb both experimental and computational variables via lesions, training parameters, pharmacology, and other experimental tools. The outcome of these studies then serves to inform the computational models and help determine the direction of future study.

One critical aspect of this process is the selection of the level of detail at which to build the model. Our modeling is nearly all based on specific neural systems – as opposed to generic neural networks – but the level of detail implemented must be appropriate given the available experimental data in order for the model to contribute meaningfully to this research approach. More abstract models of particular networks, made with relatively reduced, single-compartment neurons, are appropriate when the data include general information about neurons being excitatory or inhibitory, reasonable estimates of synaptic connectivity patterns, and neuromodulator effects that are thought to excite, inhibit, and/or affect the excitability of particular cell types. Building simpler models with fewer free parameters enables a relatively efficient exploration of what such a network can do, and how the different effects of neuromodulators, for example, could combine to produce a functional outcome that corresponds to behavioral data. Following up on hypotheses generated by such models can increase the efficiency of experimental design, ultimately producing data sufficient to build the richer and more complex biophysical models.

Biophysical models require considerably more experimental data in order to be useful. They define physical membrane properties such as surface area, capacitance, and cell morphology, model many individual mechanisms such as sodium channels, calcium diffusion, and NMDA receptors, deploy these mechanisms into or with

respect to the cell membrane, and often are morphologically multicompartmental. Oligocompartmental model neurons, in particular, are built using perhaps 2–20 compartments that may serve to accurately model spike propagation times, segregate electrotonically distant parts of the neuron, construct cells with heterogeneous channel distributions, and/or implement other phenomena in which spatial heterogeneity matters. (Neuron models with hundreds of compartments, in contrast, usually are constructed to replicate the arbor of a specific neuron measured from imaging data.) If there are constraining data for enough of these parameters, then such models are singularly powerful, as they are able to implement underappreciated computational elements like shunt inhibition, intrinsic resonance properties, and the partial isolation of spines, and at their best they can predict the network-level consequences of, for example, localized effects on ion channel properties. In the absence of sufficient data, however, such models lose most of their predictive value, as they simply contain too many free parameters which, if unconstrained, can enable meaningless fits to many datasets; simpler models should be used in such situations. Irrespective of the level of complexity, however, useful models usually do not simply replicate established data but employ their capacity to quantify and juxtapose diverse datasets in order to explain what is known and explore what that might imply. Models can range from being quite tightly based on cellular data (e.g., Li and Cleland 2013, 2017) to being more speculative (e.g., Linster and Cleland 2010), but in either case the task is to understand how best to ask the next question. While models that stand the test of time are laudable, models that are subsequently superseded by new data have served their scientific purpose well.

Over the past quarter century, we have developed computational models of many behavior-related processes within olfaction, including the cholinergic, noradrenergic, and dopaminergic modulation of bulbar circuitry (Linster and Gervais 1996; Hasselmo et al. 1997; Linster and Hasselmo 1997; Linster and Cleland 2002; Linster et al. 2003; Mandairon et al. 2006a; Escanilla et al. 2009; Linster et al. 2011; Devore

and Linster 2012; Devore et al. 2012; de Almeida et al. 2013; Li and Cleland 2013; Devore et al. 2014; de Almeida et al. 2015; Li et al. 2015; de Almeida et al. 2016), perceptual learning (Mandairon et al. 2006b), mixture processing in the olfactory bulb (Linster and Cleland 2004), the bulbar mechanisms regulating differentiation among similar odors (Cleland and Sethupathy 2006; Cleland et al. 2007; Cleland et al. 2012), the role of spike synchronization in antennal lobe odor processing (Linster et al. 1994; Linster and Cleland 2001) and synaptic plasticity in olfactory bulb and cortex (Linster et al. 2007; Linster et al. 2009; Linster and Cleland 2010; Mandairon et al. 2014), the dynamical mechanisms underlying lateral communication and synchronization across the bulbar circuit (David et al. 2008, McIntyre and Cleland 2016; Li and Cleland 2017), and the multiple concerted processes required to enable concentration invariance in odor perception (Cleland and Linster 1999; Cleland et al. 2007; Cleland et al. 2012). In each case, a critical factor affecting model validity has been the comparison between model output and behavioral results. How does one determine whether and how the values of model output variables correspond to measured indices of behavior? While this is always ultimately an experimental question, we have determined several behavioral indices that can be reliably predicted by specific output metrics from our computational models, including perceptual similarity, discrimination performance, learning rate, memory capacity, and memory persistence. For example, we first demonstrated that the pairwise overlap in neuronal activation patterns across the olfactory bulb input layer could predict pairwise perceptual similarity (Linster et al. 2001; Cleland et al. 2002). To the extent that this result is generalizable as a basic principle of olfactory coding, one then can, in subsequent studies, compare changes in pairwise overlap within the computational model to behavioral changes in perceptual discrimination. This in turn enables, for example, the effects of neuromodulators on olfactory discrimination to be modeled and tested against behavioral data (e.g., Mandairon et al. 2006a). Importantly, while this principle of pattern overlap among

glomeruli has been largely supported experimentally, its basis is inductive and it cannot be reliably extrapolated; e.g., it may not extend reliably to spatial patterns among mitral cells, or within piriform cortex. Like theoretical models in general, these models serve to organize our understanding of complex data sets until a superior theory can be constructed.

We here describe three specific examples of the modeling of olfactory behavior that provided useful insights into the underlying neural mechanisms. First, an abstract model of spike timing and oscillations in the honeybee antennal lobe explained how neuronal synchronization patterns could underlie seemingly paradoxical behavioral generalization effects observed across different odor concentrations (Linster and Cleland 2001; Cleland and Linster 2002; Linster and Cleland 2010). Second, a large-scale, reduced model of olfactory bulb outlined a feedback normalization network enabling concentration invariance in bulbar output, consistent with behavioral performance (Cleland et al. 2007). Third, a moderately detailed computational model of cholinergic modulation in the olfactory bulb glomerular layer predicted coordinated network-level and behavioral outcomes from the properties and localization of nicotinic cholinergic receptors in the olfactory bulb (Mandairon et al. 2006a; de Almeida et al. 2013; Devore et al. 2014; de Almeida et al. 2016).

Example 1: Odor Concentration and Spike Timing in the Insect Antennal Lobe

Honeybee olfaction is an important model system for olfactory learning due to its well-developed and efficient behavioral conditioning paradigms and the relatively well-understood neural circuits involved in odor learning. The behavioral relevance of spike timing regulation in olfaction was first demonstrated in the honeybee antennal lobe, in which it was demonstrated that stimulus-evoked synchronous spiking was necessary for fine odor discrimination. Specifically, in combined electrophysiological and behavioral experiments, when fine-scale spike synchrony was disrupted, bees' odor discrimination performance was impaired, even though the overall profile of

evoked activity in antennal lobe neurons remained intact (Stopfer et al. 1997; Stopfer et al. 2003). Using the same behavioral paradigm, it subsequently was demonstrated that honeybees discriminate odors better when they are presented at high concentrations than when they are presented at lower concentrations (Bhagavan and Smith 1997). Neurophysiologically, this result was counterintuitive because calcium imaging studies have shown that higher concentration odor stimuli activate correspondingly larger and more overlapping areas of the antennal lobe (Strauch et al. 2012), which, given that overlap predicts perceptual similarity, should result in poorer discrimination. Computational modeling resolved this behavioral conundrum by combining the findings of these two lines of research (Linster and Cleland 2001; Cleland and Linster 2002). The model exhibited oscillations and spike synchronization patterns similar to those recorded in the antennal lobe and demonstrated that while higher-intensity odor inputs would evoke broader neural activity overall, an increasingly narrow subpopulation of neurons within this broad ensemble would be increasingly strongly synchronized. Synchrony-sensitive follower neurons and plasticity processes responding selectively to these highly synchronous inputs would therefore interpret higher-concentration inputs as more discriminable from one another, matching behavioral observations, while blocking these synchronization processes would impair fine odor discrimination. In contrast, lower-concentration inputs would evoke weaker synchrony among antennal lobe projection neurons and generate less activity or plasticity in follower cells (Fig. 1). This work illustrated how computational modeling can fuse separate datasets derived from a common system to explain seemingly unrelated results, constructing a common theoretical basis upon which subsequent experiments can be based. Since this time, the study of spike synchronization processes within olfactory coding research has grown substantially, particularly with the elaboration of timing-dependent synaptic plasticity algorithms in the brain (Song et al. 2000; Gao and Strowbridge 2009; Linster and Cleland 2010).

Example 2: The Problem of Concentration Invariance in the Olfactory Bulb

Odorants elicit widely distributed patterns of activity across the olfactory bulb input layer, as evidenced by 2-deoxyglucose activity mapping (Johnson and Leon 2000), intrinsic imaging (Meister and Bonhoeffer 2001), and other imaging techniques. These activation patterns are substantially altered when odor concentration is changed (Johnson et al. 1999; Johnson and Leon 2000; Meister and Bonhoeffer 2001), to the extent that the pattern evoked by a given odor may more closely resemble that of a different odor than that of itself when presented at a different concentration (Cleland et al. 2007). Despite this fact, animals can identify a given odor over a reasonable concentration range, and – critically – neural response patterns at the output of the olfactory bulb are less affected by odor concentration than are those measured at the input. Interestingly, simple normalization (z-scoring) of these odor-evoked patterns rendered them reasonably consistent across concentrations (Johnson et al. 1999; Johnson and Leon 2000), and behavioral tests measuring the pairwise perceptual similarities of odorants showed that perception was better predicted by normalized activity patterns than by nonnormalized activity (Cleland et al. 2007) (Fig. 2). These results, together with physiological demonstrations that mitral cell spike rates do not monotonically increase with odor concentration (Harrison and Scott 1986; Wellis et al. 1989; Meredith 1986), suggested that these odor-specific patterns are actively normalized within olfactory bulb circuitry. Computational modeling based on these data, and on contemporary understandings of cellular properties in the olfactory bulb, demonstrated how these neural circuits in the olfactory bulb glomerular layer could perform such a normalization function. Specifically, a laterally interconnected network of interneurons, then believed to be excitatory, synapsing onto local inhibitory interneurons and with a broad distribution of lateral projection distances estimated from anatomical data (Aungst et al. 2003), was shown capable of performing feedback normalization uniformly across the bulb (Cleland et al. 2007). These simulations showed that a

Computational Modeling of Olfactory Behavior,

Fig. 1 Synchronization and odor perception in the honeybee antennal lobe. **(a)** Network diagram of honeybee antennal lobe model. The network was created based on known neuron types and was capable of generating odor-evoked, GABAergic neuron-dependent field potential oscillations that shaped spike timing as described experimentally. Briefly, input from olfactory sensory neurons (SNs) directly activates projection neurons (PNs) as well as inhibitory local interneurons (LNs). Local interneurons are reciprocally connected with each other in a feedback network which generates synchronous oscillations when activated. Local interneurons also inhibit projection neurons and are capable of synchronizing projection neuron spikes with respect to these network oscillations. Because local interneurons in the model have higher activation thresholds than projection neurons, highly activated glomeruli oscillate more strongly and the corresponding projection neurons are most strongly synchronized. The associative neuron (AN), corresponding to the reward-activated neuron VUMmx1 in honeybees, is sensitive to synchronized spike inputs. **(b)** In the model, increasing odor concentration at the input of the antennal lobe generates more widespread activation patterns and hence increased overlap among odor representations (Bi designates a lower concentration odorant, Bii a higher

concentration odorant). Each circle represents a glomerulus receiving input from sensory neurons expressing a shared olfactory receptor; darker colors symbolize stronger activation and striped glomeruli indicate glomeruli substantially activated by both inputs. Glomeruli are mapped onto a hypothetical one-dimensional circular axis of receptive field similarity (Cleland and Linster 2002). O1 and O2 denote the centers of the glomerular patterns activated by two different odors. **(c)** Increased odor concentration also generates stronger oscillations in activated glomeruli, resulting in greater synchrony among a narrower population of the most strongly activated projection neurons. **(d)** Increased synchrony leads to reduced generalization between two odors presented at higher concentrations than when presented at lower concentrations, despite their larger overlap at the input to the antennal lobe. Odor conditioning was simulated by presenting a conditioning odor stimulus to the model at a low (25% of maximum activation) or high (100% of maximum activation) intensity and training the network on the odor. Subsequently, the network was presented with a novel odor and the degree of overlap between the representations of the conditioned and novel odors was calculated (generalization). The graph shows the degree of generalization to the novel test odor after conditioning at low and high stimulus intensities. (Figures adapted from Cleland and Linster (2002))

Computational Modeling of Olfactory Behavior, Fig. 2 Normalization in the olfactory bulb glomerular layer. **(a)** Schematic depiction of odor representations in the olfactory bulb glomerular layer. Odorants are ordered along a hypothetical axis of similarity onto which individual glomeruli can be mapped. Note that this is purely for representational purposes and that such orderly mapping does not exist in the system. Glomerular activation becomes stronger and spreads by activating additional glomeruli as odor intensity increases; consequently, the overlap between two odor representations increases. **(b)** Despite the increase in overlap between odorants at higher concentrations, rats and mice can differentiate odorants better as concentration increases. The graph shows the percent correct trials in a forced choice go/no-go task in rats as a function of odor concentration (Wei et al. 2006).

(c) In certain cases, the raw and normalized activation patterns evoked by a given odorant at different concentrations are more different from one another than they are to the representation of an entirely different odorant. The graph depicts (black lines) indices of dissimilarity between glomerular activation patterns, calculated from raw or normalized 2-deoxyglucose uptake data, computed between a single odor **(a)** presented at two concentrations and between that odor and a different odor **(b)**, both presented at the same concentration (Cleland et al. 2007). For comparison, the graph also depicts (red line) the corresponding behavioral results (i.e., degree of perceptual dissimilarity) in response to the same odor pairs. The normalized activation patterns predict behavioral perception, whereas the raw data do not

partially localized network of microcircuits could underlie a nonlocalized, uniform effect, utilizing this small-world effect to normalize mitral cell odor responses in order to render them more concentration-invariant. In this example, behavioral experiments were necessary to validate the basis for the computational model by demonstrating that global normalization correctly predicted perceptual similarities. Interestingly, in subsequent experimental studies, the role of these laterally projecting interneurons in broadly

inhibiting mitral cells across the olfactory bulb was confirmed (Banerjee et al. 2015), even though the interneurons themselves since have been shown to be GABAergic and dopaminergic, rather than glutamatergic as was previously believed (Kiyokage et al. 2010). That is, the 2007 model proved correct at Marr's (1982) computational level (normalization at this level of the olfactory bulb network was required in order to explain experimental results) but not at the implementation level (the mechanism by which this

normalization is achieved was incorrect in that model). This provides an excellent example for how a model can serve its purpose, being correct at a certain level and enabling the coordinated interpretation of diverse datasets, while also becoming outdated by experimental progress and requiring update or replacement. It is also important to emphasize that computational operations in neural circuits are necessarily embedded in broader networks that can enhance, impair, or prevent their function. Concentration tolerance in olfaction, for example, is not mediated solely by this single circuit; rather, its operation depends on multiple prior circuit computations that establish important prerequisites for its success (Cleland et al. 2012).

Example 3: Effects of Nicotinic Receptor Activation on Odor Discrimination – Behavioral Experiments and Biophysical Modeling

The cellular effects of nicotinic cholinergic receptor activation in the olfactory bulb are relatively well understood (Castillo et al. 1999; Pressler et al. 2007). Nicotinic cholinergic activation opens cation currents both in mitral cells, exciting them and increasing their odor-evoked activation levels, and in GABAergic periglomerular cells, increasing their inhibition of mitral cell primary dendrites. Hence, nicotinic receptor activation simultaneously excites and (indirectly) inhibits mitral cells in the bulb – two effects that initially might appear to cancel one another out. However, computational modeling of these two neuron types embedded within their glomerular microcircuit showed that, rather than canceling each other out, these two effects complement one another (Linster and Gervais 1996; Linster and Hasselmo 1997; Linster and Cleland 2002). Specifically, while the increased inhibition on mitral cell primary dendrites sharpens mitral cell responses to odorants by suppressing weak responses, the concomitant excitation near the soma maintains or enhances the strength of response within this narrower receptive field. As a consequence, receptive fields are sharper but stronger (Mandairon et al. 2006a; de Almeida et al. 2013; Devore et al.

2014; de Almeida et al. 2016; Li and Cleland 2013). When comparing ensemble responses to multiple odorants in this model, the overlap in mitral cell activation patterns is reduced when nicotinic receptors are activated, separating the representations of highly similar odors and predicting that they would become easier to discriminate. We tested this prediction behaviorally and found that, indeed, the blockade of nicotinic cholinergic receptors in the olfactory bulb reduced rats' capacity to differentiate between perceptually similar odorants, whereas it did not affect the perception of chemically and perceptually dissimilar odor pairs. Moreover, enhancing cholinergic modulation during behavior improved rats' ability to differentiate between perceptually similar odorants (Mandairon et al. 2006a; Chaudhury et al. 2009) (Fig. 3). In this study, the known cellular effects of nicotinic receptor activation were sufficient to predict perceptual effects once constructed into an appropriate network model, suggesting that the computational model captured the essence of this neuromodulatory process. Subsequent behavioral and computational studies further suggested that this reduced overlap in bulbar representations enables more rapid cortical learning and that cortical and bulbar cholinergic modulatory responses act in concert to establish efficient and stable learning processes (de Almeida et al. 2013; de Almeida et al. 2015; de Almeida et al. 2016).

Conclusion

Computational modeling of the neurons and networks of the brain provide essential tools and frameworks for understanding the neural mechanisms underlying animal behavior. By juxtaposing diverse experimental results within appropriate theoretical frameworks, constructing functional scenarios, and assessing the likelihood and consequences of each, modeling facilitates the theoretical analysis of complex datasets and the construction of testable hypotheses, providing an essential link between physiology and behavior.

Computational Models of 3D-Cue Integration

Fulvio Domini¹ and Dhanraj Vishwanath²

¹Department of Cognitive, Linguistic, and Psychological Sciences, Brown University, Providence, RI, USA

²School of Psychology and Neuroscience, University of St. Andrews, Fife, Scotland, UK

Definition

Depth cue integration is the process by which the brain derives a three-dimensional property (e.g., depth, slant and curvature) from distinct image measurements, often referred to as depth cues. Individual depth cues are thought to result from independent processes of image formation. The goal of a computational model of cue integration is to describe the brain mechanisms which combine different depth cues into a single estimate of a 3D property. A valid model must be based on a testable normative theory identifying (1) the nature of the 3D information provided by separate modules, (2) the goal of the computation, (3) the computational algorithms that underlie integration, and (4) a plausible neural implementation in a biological system.

Detailed Description

Depth Cues and Multiple Processes of Image Formation

The light reflected by surfaces of environmental objects projects patterns to the point of observation that are registered as retinal images. The structure of these images depends on the complex interplay of several factors related to the material composition of the projecting surfaces and their spatial relationship relative to the point of observation. These factors are responsible for independent processes of image formation that only have in common the 3D structure of the object from which they generate. To illustrate this, consider Fig. 1a. The material composition of the 3D object is such that its surface is covered with circular texture elements. The retinal projections of these elements are ellipses whose aspect ratio and orientation depend on the slant and tilt of the underlying 3D surface (Fig. 1b). This pattern of elliptical shapes – the texture gradient – therefore carries information about the 3D surface. This aspect of image formation is distinct from the

one also shown in Fig. 1b which derives from the same 3D structure but results in a different image information: shading. If the object surface is composed of a uniform matte material, then the relative orientation between local surface patches and the direction of the illuminant determines the intensity of the light that these patches reflect. For the smooth surface, the variation in local surface orientation relative to the illuminant and viewing direction results in the familiar smooth variation of light intensity (shading) observed on the image projection (Fig. 1b).

The image patterns arising from these distinct aspects of image formation are often referred to as depth cues. Texture and shading are examples of depth cues arising from static *monocular* image formation processes resulting from the specific relationship between viewpoint, surface shape, material composition, and ambient light. In contrast, two other depth cues (binocular disparity and motion parallax) depend on image formation processes deriving solely from the relative shift in the image of projected points between two distinct views. For binocular disparities, this shift is

C

Computational Models of 3D-Cue Integration, Fig. 1 (a) A 3D surface projects images onto the retinae of the left and right eye (represented by planar surfaces). z represents the observer's gaze direction, (x, y) the frontoparallel plane, and $\vec{z}(x, y)$ the depth-map. (b) The

retinal images (top) can be decomposed into distinct sets of image measurements, commonly referred to as depth cues, capturing independent processes of image formation (bottom)

recorded instantaneously through a comparison of the right and left retinal images. For retinal motion, the shift is registered monocularly between two instants of time.

Depth Cues and Mappings to External 3D Structure

3D structure can be operationalized in terms of either the first-order property of a “depth map” of discrete points, or higher order properties such as the slant of a planar surface, or the curvature of a nonplanar surface. Depth cues result from a mapping from these 3D properties to two-dimensional retinal image patterns. However, as suggested above, the information carried by this mapping is also mediated by other factors that are independent from the 3D structure of objects, such as material properties, illuminant characteristics, location, and motion of the observer. We define these as scene parameters.

If we define a 3D property, for example, a depth map $\vec{z}(x, y)$, and a set of scene parameters $\vec{p}_i$, a depth cue i can be formally specified as a set of image measurements $\vec{c}_i(x, y)$ defined at each image location (x, y) resulting from an image formation process $\vec{c}_i(x, y) = f_i(\vec{z}(x, y), \vec{p}_i)$. Unless the scene parameters $\vec{p}_i$ (e.g., material property, illuminant) are specified, depth cues are inherently ambiguous.

Consider, for example, the texture cue, which can be defined as a set of orientations, sizes, aspect ratios, and distributions of image texels $\vec{c}_T(x, y)$. The relevant scene parameters for the texture cue are the texel properties on the 3D surface $\vec{p}_T(x, y)$. Without some knowledge of $\vec{p}_T(x, y)$, it is impossible to recover or infer $\vec{z}(x, y)$, since the shape and distribution of image texels depend both on the surface structure and the shape and distribution of surface texels. In the example of Fig. 1, the smooth variation of orientations and aspect ratios of image texels can only be mapped back to the generating 3D structure if surface texels are assumed to be circular and uniformly distributed over its surface. Similarly, other cues are also intrinsically ambiguous: the shading cue is ambiguous since the image luminance gradient depends on the rate of variation of the local surface orientation as well as the material composition of the

object and the characteristics of the ambient illumination; patterns of retinal motion depend on the observer’s speed of motion; binocular disparities for a given object depend on the square of the distance to the object from the observer.

Assuming that each image measurement type $\vec{c}_i(x, y)$ derives from an independent and distinct neural process, the problem is to understand how the visual system analyzes and combines the inferred 3D structure from each measure (depth cue) to achieve a unique 3D interpretation.

Normative Theories of Cue Integration

In the tradition of the computational approach introduced by David Marr (Marr 1982), it is important to specify both the goal of the visual system and the algorithmic process when encoding 3D information. Vision scientists mostly agree that locating objects within the scene and estimating their 3D structure mainly serves the purpose of allowing efficient interactions with the environment. An obvious solution is to postulate that the visual system derives accurate (unbiased) estimates of 3D properties from retinal projections. In reference to the previous formulation, this means deriving the actual depth map $\vec{z}(x, y)$ from the depth cues. However, we saw that without knowledge of the scene parameters, $\vec{p}_i$, depth cues underspecify $\vec{z}(x, y)$. Depending on the specific cue and the viewing conditions, knowledge of the scene parameters is either partial or depends on having learnt the statistical regularities of the environment.

The analysis of single cues in terms of world to image mapping was inspired by Gibson’s seminal analysis of image gradients and how such gradients can directly specify certain aspects of the 3D structure of the external environment (Gibson 1950, 1966). Much of the detailed computational analysis and development occurred in the field of machine vision and first wave artificial intelligence. For example, Horn and Takeuchi’s analysis of the shading cue (Horn 1986) was followed on by other work on texture, motion, and disparity (see Howard and Rogers 2002). These deterministic models identified the dependence of the mapping on a range of viewing parameters and the necessity of underling uniformity assumptions

(e.g., isotropy, surface continuity, and uniform reflectance) necessary for restricting possible solutions of the inherent one-to-many mapping.

An alternative algorithmic approach to deriving the 3D object structure is based on a probabilistic formulation of the problem. Consider again the texture cue example shown in Fig. 2. The retinal image depicted at the bottom of Fig. 2a could be interpreted as a flat surface (interpretation 1) across which texture elements systematically vary in shape (texture elements are idiosyncratically compressed and denser at the edges). Although this interpretation is correct (the surface on which this

figure is printed/displayed is indeed flat), we perceive the pattern as a curved surface. This is presumably because the visual system prefers a 3D interpretation (interpretation 2) where the shapes of texture elements are inferred to be similar to each other in size and orientation (uniformity) and distributed evenly (isotropically) across a surface (Knill 1998).

This preference could arise from learning the most common properties of textures present in the world. The visual system is said to prefer interpretation 2 because it represents a texture pattern that is more probable to exist in the world than the

Computational Models of 3D-Cue Integration, Fig. 2 A texture pattern measured on the image can be projected back onto a range of possible 3D interpretations. In the subset depicted, one interpretation corresponds to the image plane (1), one to the veridical solution (2), and one to a more elongated object (3). The texture pattern resulting from the back-projection can be analyzed in terms of how probable it is according to the natural statistics of the environment. If knowledge of these statistics is accurate, then the most likely 3D interpretation is, on average, veridical (solid curve). However, any given

image instance will yield a likelihood function peaked at a non-veridical solution (dotted curve), such deviation being smaller for a reliable texture pattern (a) than an unreliable texture pattern (b). (c) When multiple cues are present on the image, the likelihood functions $P(\vec{c}_i|z)$, where $i = T, S, D, M$ will be peaked at different values (dotted curves) that all deviate from the veridical solution (vertical dotted line). However, the joint likelihood distribution $P(\vec{c}_T, \vec{c}_S, \vec{c}_D, \vec{c}_M|z)$ (solid curve) is more precise and peaked at a value closer to the veridical solution

one implied by interpretation 1, although both are equally plausible from a theoretical standpoint. Similarly, an interpretation of a very deeply curved surface (interpretation 3) is also considered less probable because it would imply an underlying surface texture pattern that is also non-uniform and nonisotropic. In other words, the problem can be cast as determining the most likely 3D interpretation based on the statistical likelihood in the external world of different patterns of texture elements implied by the “unfolded” surface for each interpretation.

If the visual system has accurate knowledge of the statistical distribution of scene parameters and their mappings to retinal images (e.g., Likelihood distributions of texture patterns), then this 3D interpretation will on average correspond to the accurate 3D structure (i.e., it will be unbiased). Note, however, that given the stochastic nature of this postulated process, any given 3D estimate will necessarily deviate from the accurate solution. In Fig. 2a, the solid curve represents the ideal case in which the likelihood distribution is peaked at the accurate 3D solution. In practice, the likelihood function will be peaked at a different value (dotted curves in Fig. 2) because, for example, texture elements on an actual 3D surface will never perfectly match the criteria of homogeneity and isotropy. Over a large number of estimates of similar 3D structure, or multiple trials in a laboratory experiment where the surface textures are generated by the same random process (as for the object in Fig. 1), the distribution of estimates $P(\hat{z}|z)$ will match that of the unbiased likelihood function represented by the solid curve. The variability of trial-by-trial estimates will depend on the specific nature of the surface texture patterns. For example, the image in Fig. 2b (bottom) results from the projection of a surface composed of random points rather than circular dots (Fig. 2a). When back-projected on possible 3D interpretations, the distributions of the resulting “unfolded surfaces” are statistically similar, hence the flat likelihood function. In this case, any given estimate based on the likelihood distribution will deviate substantially from the accurate solution (Fig. 2b, dotted line).

The above analysis leads to a formulation of the problem of cue integration as that of finding the most probable 3D interpretation given multiple image measurements. The debate in the early 1990s was largely about whether this process involved a nonlinear and interactive process dubbed “strong fusion” or a modular and linear combination process dubbed “weak fusion” (see Clark and Yuille 1990). While some early research suggested a nonlinear regularization model (e.g., Bülthoff and Mallot 1988), later work championed the linear model which was developed and validated based on an approach using Bayesian probability theory (Landy et al. 1995; Clark and Yuille 1990).

The Bayesian approach allows a formal definition of the problem of inference of 3D structure from individual image cues in probabilistic terms. Given a set of image measurements $\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n$, the probability of a 3D interpretation $\vec{z}$ is:

$$P(\vec{z}|\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n) = \frac{P(\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n|\vec{z})P(\vec{z})}{P(\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n)}$$

$P(\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n|\vec{z})$ is the likelihood function, which quantifies the probability of making the observed set of image measurements given a specific interpretation $\vec{z}$. $P(\vec{z})$ is the prior probability of the given 3D structure $\vec{z}$ in the environment independent of the image data. $P(\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n)$ is the probability of making the set of image measurements, which is a constant since it does not depend on the depth map $\vec{z}$. Given this formulation, the problem of finding the Euclidean structure that has generated a given image is to seek $\hat{\vec{z}} = \underset{\vec{z}}{\operatorname{argmax}} P(\vec{z}|\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n)$, defined as the Maximum A Posteriori (MAP) estimate. In absence of knowledge about the a priori probability of 3D structures in the environment, the term $P(\vec{z})$ is non-informative (uniform distribution). In this case, this process reduces to finding the most likely solution $\hat{\vec{z}} = \underset{\vec{z}}{\operatorname{argmax}} P(\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n|\vec{z})$, defined as Maximum Likelihood Estimate (MLE).

If $\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n$ are conditionally independent, that is, the scene parameters affecting one cue are independent from those affecting another (e.g., the surface material is independent from the motion of the observer or the direction of the illuminant), then the likelihood function of the image can be expressed as the product of the likelihood functions $P(\vec{c}_i|\vec{z})$ associated with each individual cue:

$$P(\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n|\vec{z}) = P(\vec{c}_1|\vec{z})P(\vec{c}_2|\vec{z}) \dots P(\vec{c}_n|\vec{z})$$

In this simplified version of the problem, finding the most likely 3D interpretation requires that individual modules estimate the actual likelihood functions, which requires a knowledge of the image formation function and the distribution of scene parameters.

If the likelihood functions are Gaussian distributions peaked at $\hat{\vec{z}}_i$ with variance σ_i^2 then the combined likelihood $P(\vec{c}_1, \vec{c}_2, \dots, \vec{c}_n|\vec{z})$ is peaked at $\hat{\vec{z}} = \sum_{i=1}^n w_i \hat{\vec{z}}_i$, where $w_i \propto 1/\sigma_i^2$ and $\sum_{i=1}^n w_i = 1$. Importantly, the combined estimate $\hat{\vec{z}}$ is closer to the accurate (unbiased) solution than each single-cue estimate and the variance of the combined likelihood smaller than the variances of the single-cue likelihoods. Specifically: $1/\sigma_c^2 = \sum_{i=1}^n 1/\sigma_i^2$ (see Fig. 2c).

This equation provides a possible heuristic implementing MLE cue combination: individual MLEs are combined through a weighted average, where each weight is inversely proportional to the variance of the likelihood function. Figure 2c illustrates the Bayesian cue combination regime in graphical form. Each cue measurement of the image leads to an estimate of the underlying depth structure, where each estimate will deviate from the accurate solution due to stochastic noise (even though the underlying likelihood function for each cue estimator is unbiased), but the combined estimate will converge on the accurate solution.

The MLE model has been tested by assuming independent unbiased estimates of texture and disparity, texture and motion, disparity and motion in the visual modality, as well as

integration of 3D information between the sensory modalities (Landy et al. 2011). This method can be generalized to dependent cues (motion and disparity), to non-Gaussian functions with long tails, and to the full Bayesian model when the image data is unreliable (see Landy et al. 2011). Other additional rules to deal with special cases have also been proposed. For example, in the case of cue inconsistency, the robustness rule suggests that when two cues have very different reliabilities, the more precise cue could overrule the less precise one (Landy et al. 2011).

Challenges of the Bayesian Approach

The strength of the Bayesian framework is that it provides a clearly reasoned normative theory of cue integration. However, there are challenges to this framework posed by both theoretical and empirical considerations. From a theoretical perspective, the basic assumption of the Bayesian approach is that the visual system has learnt an accurate mapping between single cues and 3D properties. This requires the internalization of the accurate statistics of the object-to-image mappings, material and spatial properties of objects, etc., through a process of implicit or explicit learning. The internalization of object-to-image mappings presupposes access to error signals, such as arising from incorrect motor executions. While such error signals may be readily available within the graspable region of the agent, it leaves open the question of how information beyond this region is learned, where such feedback is not always available but where vision still delivers useful 3D information.

A further assumption of this model is that it requires on-line instantaneous access to unbiased probability distributions of the mappings (likelihood functions) between a large variety of possible 3D interpretations and 2D patterns. There have been some preliminary proposals on how this might occur (Knill 1998; Landy et al. 2011) and recent advances in machine learning suggest that vast numbers of mappings can indeed be learnt. The challenge, however, is to show whether such learning systems can generalize to

complex domains and be made compatible with the overall algorithmic structure of Bayesian integration.

Other complications for the Bayesian approach come from empirical observations that seem at odds with its basic assumptions and predicted outcomes. First, the main assumption of unbiased estimates from individual cues does not seem to hold in a large number of studied examples in shape from texture (Todd 2004), shape from motion (Domini and Caudek 2003), and shape from disparity (see Howard and Rogers 2002, on depth constancy). Moreover, studies show that even when multiple cues are combined, they lead to systematic biases in perceptual judgments (Bülthoff and Mallot 1988; Todd 2004). Though some of these results may be interpreted in the Bayesian framework by considering the influence of priors (e.g., the “flatness” prior), such priors are invoked in an ad-hoc manner.

A ubiquitous example of a departure from the prediction of the Bayesian approach is the perception of pictorial depth when viewing depictions of 3D scenes rendered on a flat surface (e.g., photographs). Within the Bayesian framework, the information present in this stimulus can be represented by two likelihood functions, one for depth estimates from monocular cues taken together and another from binocular disparity. The latter is sharply peaked at zero depth since disparity specifies a flat surface. The combined likelihood function predicts a depth interpretation (or combined peak) lying somewhere between zero depth and the peak from the monocular information, but biased more toward the zero-depth interpretation, because disparity is usually the most reliable signal. This implies that depth should appear significantly flatter or squashed in the *z*-direction yielding distortions in perceived 3D object and layout compared to viewing the real scene. Removing the disparity cue by closing an eye should shift the peak to that specified by monocular cues causing the perception of significantly increased depth and changes in perceived 3D shape/layout more closely matching the real scene. However, consistent with informal observation, this prediction has been disconfirmed in multiple experimental paradigms (see Vishwanath 2014).

More generally, the Bayesian approach’s assumption that the aim of depth cue integration is to derive a single accurate depth map of the 3D scene does not appear to comport with empirical evidence that suggests multiple depth representations or maps that are invoked under different behavioral conditions (see Loomis et al. 1992; Glennerster et al. 1996). For example, while observers can accurately blind-walk to two pre-viewed markers at different distances (up to a range of at least 20 m), their visual estimates of the depth separations between the same two markers is highly underestimated (Loomis et al. 1992). Another vivid example of the potential for multiple dissociated representations and associated biased estimation is demonstrated in Fig. 3 (Di Luca et al. 2010). Here, it is evident that different cues deliver widely different but stable percepts of curvature, slant and depth even when the underlying 3D structure from which the images are generated is identical. This suggests that different cues may be specialized towards derivation of different and distinct aspects of 3D structure such as 3D curvature or slant, rather than the generic derivation of a single depth map. This could explain specific biases in 3D judgments with specific cues.

A significant challenge to computational approaches that aim to explain the psychology of 3D vision is that they must ultimately be compatible with important aspects of the appearance and phenomenology of 3D objects and space. In the Bayesian approach, the theoretical assumption that depth cue integration derives from a stochastic process underlies the empirical assumption that the variability in subject responses to multiple presentation of a stimulus arises from the random sampling of an underlying likelihood probability distribution (Landy et al. 2011). This implies that perceptual estimates of depth or 3D shape from the very same stimulus (single or multi-cue) with fixed viewing parameters are necessarily different from instance to instance. This does not seem to comport with our phenomenology in most cases of stable 3D structure for a given stimulus.

Computational approaches must also ultimately provide explanations for the compelling differences in the appearance of 3D space under

Computational Models of 3D-Cue Integration,

Fig. 3 Rendering of the same 3D paraboloid when it is specified by only texture or shading information. The textured object appears significantly deeper than the shaded one, and yet the latter looks “pointier” (higher curvedness at the tip) than the former

different conditions; for example, the vivid immersive and tangible depth that is induced under binocular but not monocular viewing of real scenes. Because the Bayesian approach regards all cues (monocular and binocular) to be functionally and computationally equivalent at the stage of integration (Landy et al. 1995) and assumes the derivation of a single 3D representation, it struggles to account for differences in appearance across different viewing and stimulus conditions.

Alternative Models

Alternative models must replicate empirical results that seem to support the Bayesian model predictions, such as the claim that combined-cue estimates are more reliable (less noisy) than individual cue estimates. But they must, in addition, provide a theoretical framework which can account for widespread perceptual biases in a non-ad hoc way, and which can accommodate a more parsimonious and realistic framework for learning object-to-image mappings. They must also be able to point to ways in which other aspects such as multiple representations and features of visual appearance can be accounted for.

An alternative approach to the modelling of cue integration is to drop the notion that it is aimed at deriving a single accurate (unbiased) reconstruction of the scene, but that, instead, the system simply learns mappings between image measures and physical structure through trial and error as a results of repeated interactions with

physical objects. Formally, the visual system learns independent mappings relating image measurements $\vec{c}_i$ to 3D estimates $\vec{z}_i$ such that these estimates are proportional to the 3D property: $\vec{z}_i = f_i(\vec{c}_i) = \lambda_i \vec{z}$. These mappings are learnt in ideal conditions, that is, (1) within the personal space of the agent, where errors arising from unsuccessful motor actions can modify the mapping and (2) within typical ranges of scene parameters such as the motion of the observer, the material properties of objects, and the illuminant. When the ideal conditions for cue i are met, the proportionality factor λ_i takes on a value close to one. For example, λ_i is close to one for disparity processing when the object is at the most frequent grasping distance and for motion when the observer moves at an average speed. In contrast to the Bayesian approach, each module does not provide an unbiased estimate of 3D properties, but an estimate proportional to the 3D property through an unknown proportionality factor λ_i .

If single-cue mappings are assumed to be learnt simultaneously as components of a general mapping, we can define the function $\vec{z}_c = F_c(f_1(\vec{c}_1), f_2(\vec{c}_2), \dots, f_n(\vec{c}_n)) = F_c(\lambda_1 \vec{z}, \lambda_2 \vec{z}, \dots, \lambda_n \vec{z})$ characterizing this mapping based on normative criteria. The criteria are (1) that this function is maximally sensitive to variations in the value of the 3D property $\vec{z}$ relative to variations of the scene parameters λ_i and (2) it is proportional to the 3D property $\vec{z}$. These criteria can be met by finding the function $F_c(\lambda_1 \vec{z}, \lambda_2 \vec{z}, \dots, \lambda_n \vec{z}) = \lambda_c \vec{z}$ maximizing $\frac{\lambda_c}{\sigma_{\lambda_c}}$, where σ_{λ_c} is the standard deviation of λ_c . Note

that the variability of λ_c depends on the variability of the scene parameters, quantified in terms of variances $\sigma_{\lambda_i}^2$. It can be shown that $\frac{\lambda_c}{\sigma_{\lambda_c}}$ is maximized if:

$$\begin{aligned}\hat{\vec{z}} &= \beta \sqrt{\sum_i \frac{f_i(\vec{c}_i)^2}{\sigma_{\lambda_i}^2}} = \beta \sqrt{\sum_i \frac{(\lambda_i \vec{z})^2}{\sigma_{\lambda_i}^2}} \\ &= \lambda_c \vec{z}\end{aligned}$$

where β is a constant. This model of 3D cue integration differs from Bayesian models in two ways. First, since the unknown proportionality factor λ_c is most often *not* equal to 1, the model output is in general biased, except when the visual system is operating within the ideal scene conditions on which the system parameters have been learned. Second, it is a deterministic and not a stochastic model, in that, given a visual input, it provides a single estimate, not a probability distribution. In contrast to the MLE, the variances $\sigma_{\lambda_i}^2$ are not associated with likelihood distributions derived for each specific stimulus estimated in real time, but are fixed parameters slowly learned and modified through interactions with the environment. The alternative approach described here is an adaptation of a model of cue integration termed the Intrinsic Constraint (IC) model (Domini and Caudek 2011, 2013).

Can such a model account for the main achievement of the Bayesian approach, namely, predicting the reduced depth-discrimination thresholds from single-cue stimuli to combined-cue stimuli? According to the Bayesian approach, this reduction is due to the shift in variability in trial-to-trial responses from single cues to combined cues and, particularly, the improvement in reliability when cues are combined. A pervasive technique for estimating the variability of a sensory estimate within the MLE approach is the Two-Interval Forced Choice (2IFC) psychometric procedure, where on a given trial a fixed standard stimulus is compared to a variable comparison stimulus. Using this method, the standard deviation of the underlying single and combined cue likelihoods are estimated as the Just Noticeable Difference (JND) in responses (the depth difference between comparison (z_C) and standard (z_S))

yielding an 84% discrimination rate (see Fig. 4a)). If JND_i are single-cue estimates of the noise standard deviation, then MLE predicts that the combined stimulus should give rise to: $1/JND_c^2 = \sum_{i=1}^n 1/JND_i^2$ as indeed verified in several studies (see Landy et al. 2011)).

Unlike the MLE approach, where this prediction is modelled to arise from variability in the cue-specific depth estimator from trial to trial, the IC model proposes that variability in a 2IFC task arises from response variability as a result of task demands (e.g., retaining in memory a perceived 3D property for two interval comparisons). This variability is a function of the depth gain relating each cue (or combination thereof) with depth estimates. To understand this, consider again the previous equation. Since β , λ_i , and $\sigma_{\lambda_i}^2$ are unknown parameters, considering the depth between two points (not the entire depth map), the equation can be rewritten as:

$$\hat{z} = \sqrt{\sum_i (k_i z)^2} = Kz$$

where k_i are unknown gains associated with each cue and $K = \sqrt{\sum_i k_i^2}$ is the gain of the combined stimulus. In this case, the difference between the estimated depths of the comparison and standard stimuli need to yield $\Delta \hat{z} = \sigma_N$, where σ_N is the standard deviation of the task-related noise. Since $\Delta \hat{z} = K \Delta z = K(z_C - z_S)$ the JND (defined as $z_C - z_S$) is inversely proportional to the gain: $JND = \frac{\sigma_N}{K}$ (Fig. 4b). Since for single cues $JND_i = \frac{\sigma_N}{k_i}$ and for combined cues $JND_c = \frac{\sigma_N}{\sqrt{\sum_i k_i^2}}$ it follows that: $1/JND_c^2 = \sum_{i=1}^n 1/JND_i^2$, matching the prediction of the Bayesian model.

In general, for conditions where there are only small conflicts between depth cues, this model makes exactly the same predictions as the MWF, that is, weighted cue combination where the weights are inversely proportional to the squared JNDs.

Although this model makes the same predictions as the Bayesian models regarding discrimination thresholds, there are important differences. First, the Bayesian probabilistic approach

Computational Models of 3D-Cue Integration, Fig. 4 (a) The MLE approach predicts that the distribution of responses resulting from repeated viewing of the same 3D object $P(\hat{z}|z)$ matches the likelihood function $P(\vec{c}_i|z)$. If the likelihood function is Gaussian, the Just Noticeable Difference (JND) between a fixed standard stimulus z_s and a comparison stimulus z_c is a measure of the standard deviation of the likelihood function. (b) According to the IC approach, repeated viewing of the

same 3D object leads to a negligible variation of the percept. Instead, the variability in the responses of a comparison task is the result of decision noise that for similar stimulus magnitude has a fixed standard deviation σ_N . Since according to IC model, the 3D estimates $\hat{z}$ are related to the world property z through a gain K that in general is different from unity, the JND is an indirect measure of the gain ($JND = \frac{\sigma_N}{K}$)

assumes the existence of underlying cue likelihood distributions that can be directly inferred from JND measurements for specific stimuli. The alternative deterministic approach does not require the existence of likelihood functions and JND measurements are not claimed to represent noise in the underlying estimates or likelihood distributions, but instead in the psychophysical decision process. Second, it makes different predictions regarding biases in 3D estimates. For example, it predicts that combined stimuli always look deeper than single-cue stimuli, since depth estimates are added through the Pythagorean sum (Domini and Caudek 2011, 2013) so that the gain of the combined stimulus is always larger than the gain of the single-cue stimuli. This property of the model, combined with the new interpretation of JNDs, leads to a second counterintuitive prediction: the perceived depth of two stimuli is the

same when the ratio between the simulated depths matches the ratio between the JNDs of the two stimuli (Domini and Caudek 2013).

Another paradox in depth cue integration (mentioned in the previous section) that can be predicted within the IC framework is the case of pictorial depth perception where the integrated depth estimates in pictorial space appear unaffected by the strong binocular disparity signal specifying zero depth (flatness). Specifically, judged pictorial depth does not change between monocular and binocular viewing (see Vishwanath 2014), contrary to the prediction of the Bayesian (MLE) model. The IC model predicts no perceived depth difference between monocular and binocular viewing of pictorial images since monocularly the disparity gain is zero ($k_d = 0$), and binocularly, disparity specified depth is equal zero ($z_d = 0$), such that the disparity

term in the Pythagorean sum is zero in both cases and does not contribute to the depth interpretation.

The model is also compatible with the observation described previously (Fig. 3) that perceived 3D shape for a given object appears different depending on the underlying cue specifying 3D shape. The IC model can explain these differences in terms of gain. When depth or slant is concerned, the gain of the texture stimulus is much higher than the gain of the shading stimulus, presumably because shading does not encode depth directly, and therefore a larger depth (higher slant of sides) is perceived. On the other hand, the gain for curvature is larger for the shading than the texture cue, since shading encodes curvature directly (Di Luca et al. 2010), and therefore the tip of the shaded stimulus appears pointier.

Future Directions

Looking to future, beyond accurately modeling quantitative judgments of 3D properties, any comprehensive computational theory of cue integration must also be able to provide an operational understanding of the significant differences in visual appearance of three-dimensionality under different combinations of depth cues. For example, human observers report a vivid, tangible, and immersive appearance to objects and the spaces between them viewing real objects binocularly (where depth cues are consistent) compared to viewing a high-resolution pictorial depiction of the same scene (depth-cue conflict), despite the fact that the perception of 3D shape and layout in the two cases are very similar (Vishwanath 2014). One way in which these differences may be accommodated within a computational model of depth-cue integration is to drop the assumption of the Bayesian model that the visual system derives a single 3D map. Instead, depth-cue integration is directed at creating two distinct depth maps: a “relative” depth map that encodes 3D properties only up to a uniform scaling factor and a “scaled”

depth map where 3D properties are scaled in units relevant to the motor plant. Recent evidence suggests that such a model can more effectively explain variations in qualitative appearance as well as how differences in qualitative appearance are correlated with the efficacy of the representations for 3D shape judgments and motor interaction (Vishwanath 2005, 2014).

Summary

The most widely accepted model of depth cue integration claims that the computational goal of depth cue integration is the reconstruction of a single accurate representation of the visual scene. It assumes that estimates from single cues are stochastic samples from underlying probability distributions (likelihood functions) and that the distributions arise from unbiased scene-to-image (cue) mappings. The theoretical challenges to this model remain as to how vast numbers of stimulus-specific unbiased likelihood mappings are learned and accessed and how probabilistic variability in depth estimates can be reconciled with the stable perception of 3D objects and layout. The empirical challenges are in explaining the evidence showing a ubiquity of biases in 3D judgments, evidence of multiple distinct 3D representations, and the inability of the Maximum Likelihood approach to address differences in visual appearance under different cue combination regimes. Alternative approaches that rely on a deterministic multi-representation cue integration regime may provide clues to how these challenges can be met.

Computational Models of Auditory Stream Segregation

James Rankin¹ and John Rinzel²

¹College of Engineering, Mathematics and Physical Sciences, University of Exeter, Exeter, UK

²Center for Neural Science and Courant Institute of Mathematical Sciences, New York University, New York, NY, USA

Definition

Auditory stream segregation is a fundamental process that allows us to segregate and focus on distinct sound streams (e.g., voices) in a dynamic noisy environment. Stream segregation has been widely studied with the auditory streaming paradigm, a relatively idealized stimulus for which two sequences of pure tones can be segregated in different streams. Our understanding – still far from complete – of this process is informed by a wealth of behavioral experiments, electrophysiology, brain imaging, and theoretical modelling. This review will highlight modelling efforts that have advanced our understanding of this important dynamical process.

Detailed Description

Auditory scene analysis involves segregating a complex scene into objects or streams (recent reviews: Bendixen (2014) and Snyder and Elhilali (2017)). A valued paradigm involves segregating two interleaved sequences of A tones and B tones repeating in an ABA_n pattern and separable by a perceived difference in pure tone frequency and timing (auditory streaming, Fig. 1a) (van Noorden 1975). The sequence can be perceived as integrated into one or as segregated into two streams (Fig. 1b). The initial percept is typically integration, but as time proceeds (over ~10 s), a

A Auditory streaming: ABA_sequence**B** Perceptual interpretations (percepts)**C** van Noorden organisation (redrawn; van Noorden 1975)

Computational Models of Auditory Stream Segregation, Fig. 1 Behavioral characteristics of auditory streaming experiments. (a) Stimulus paradigm where low-frequency A tones, high B tones (separated by the difference in tone frequency DF), and silences () each of 100 ms repeat in an ABA_triplet pattern with a presentation rate PR = 10 Hz. (b) Stimulus is perceived as either one integrated stream ABA_ABA... or two segregated streams A_A_A_A... and _B_B_B_B... (c) Schematic diagram of the perceptual regions in terms of PR and DF, redrawn after van Noorden (1975). Predominantly integration for small DF and segregation for large DF (with dependence on PR), while either is possible (ambiguous) at intermediate ranges. (d) Perceptual reports for 90 s of a single trial. Initial percept is integrated (bias to integration)

perceptual transition to segregation becomes more likely, a phenomenon called “buildup” (Anstis and Saida 1985). Buildup occurs more rapidly with a large difference in tone frequency (DF) between A and B (Fig. 1e) and at faster presentation rates. The bias in perception toward

D Percept reports (human data, Rankin et al 2015)**E** Trial-averaged build-up function (model, Rankin et al 2017)**F** Distribution of perceptual durations (human data N=15, Rankin et al 2015)

followed by a switch to segregated within first ~10 s (buildup phase). Subsequently perception alternates every ~2–5 s between integrated and segregated (bistability) if DF is not too large or small (Data from Rankin et al. (2015)). (e) Buildup function with initial bias to integration (proportion of segregation is low initially). Trial averaging across abrupt switches results in a smooth buildup function. Probability of segregation builds up over time (faster at large DF). Converges to the proportion of segregation in post-buildup alternations (Panel reproduced from Rankin et al. (2017)). (f) Stochasticity is characterized by a log-normal distribution of perceptual durations (data normalized by the mean duration for each individual to account for intersubject variability) (Panel reproduced from Rankin et al. (2015))

integration at low DF, segregation at high DF, and ambiguity at intermediate values was characterized in the so-called van Noorden diagram (Fig. 1c). The first perceptual switch, typically from integrated to segregated, is followed by persistent alternations between the two interpretations

(auditory bistability) (Fig. 1d). Pressnitzer and Hupé (2006) showed that auditory bistability shares the characteristics of perceptual bistability: exclusivity (one percept at a time), inevitability (of switches), and randomness (of percept durations) (Leopold and Logothetis 1999). The stochasticity of switching times is characterized by a log-normal distribution (Fig. 1f). These characteristics hold for a broad class of bistable visual stimuli including binocular rivalry (Leopold and Logothetis 1999), ambiguous figures (Long and Toppino 2004), moving plaids (Hupé and Rubin 2003), and gratings (Meso et al. 2016).

Electrophysiology has revealed the neural activity underlying auditory streaming. Trial-averaged recordings with short stimulus presentations (< 20 s) show a dependence on DF and PR in the primary auditory cortex (A1) in awake monkeys (single-electrode recordings) (Fishman et al. 2001, 2004; Micheyl et al. 2005) and in anesthetized rodents (voltage-sensitive dye imaging) (Farley and Noreña 2015). In a data-driven statistical model, A1 responses were interpreted using neurometric functions that mimic the time course of buildup in Micheyl et al. (2005); Pressnitzer et al. (2008); see (Deike et al. 2012) for a discussion of the computation of buildup functions. Recently, imaging approaches have shed light on the network of brain areas involved in streaming with fMRI (Kashino and Kondo 2012), the effects of attention on neural representations of streams with MEG (Billig et al. 2018) or with magnetic resonance spectroscopy (Kondo et al. 2018), and the role of oscillations in encoding streams with EEG (Costa-Faidella et al. 2017) (comprehensive review: Snyder and Elhilali (2017)).

This review explores the various modelling approaches used to study auditory streaming, from signal processing and temporal coherence to neuronal competition and statistical models.

Signal Processing and Temporal Coherence

Various models have been proposed that exploit multiple stages of processing with filter banks and

nonlinear transformations to model auditory stream segregation (e.g., Beauvois and Meddis (1991), McCabe and Denham (1996), Elhilali and Shamma (2008); review: (Szabó et al. 2016)). While the different stages in these models are often mapped to different stages of processing in the auditory pathway, the computations performed do not have a firm link to neural computations. A central focus of these studies has been to reproduce the dependence (van Noorden 1975) of perceptual bias (toward integration or segregation) on DF and presentation rate (Elhilali and Shamma 2008), the dynamics of buildup (McCabe and Denham 1996), or both (Beauvois and Meddis 1991). These frameworks have been extended to incorporate a representation of temporal coherence (the common onset of auditory events) (Elhilali et al. 2009; Ma 2011), which is a strong cue for the integration of streams. Several of these frameworks have been used to explore auditory scene analysis for stimuli that are significantly more complicated than the example of ABA_triplets shown in Fig. 1a. For example, the crossing-bouncing illusion reported in van Noorden (1975) (rising and falling sequences of tones are perceived as crossing over or bouncing) has been explored with models (Elhilali and Shamma 2008; McCabe and Denham 1996). Recently the temporal coherence framework was used to explore the segregation of complex sound sources, including speech (Krishnan et al. 2014).

Neuronal Competition

Competition-based models proposed for visual bistability (e.g., binocular rivalry) incorporate mutual inhibition, slow adaptation, and noise (Laing and Chow 2002). In noisy competition-based dynamics, a slow adaptation process sets durations and produces switch statistics (Shpiro et al. 2009). The phenomenological model presented in Mill et al. (2013) treats buildup and subsequent bistability separately. The pattern discovery stage addresses algorithmically the formation of the different perceptual patterns during buildup, and the initial bias to integration

emerges from this process (albeit without a link to neural computations). Abstracted units assigned to each discovered perceptual pattern enter into competition through the mechanisms described above.

Our recent study introduced the first neuromechanistic competition model of auditory bistability (Rankin et al. 2015), a departure from percept-based rivalry models (Laing and Chow 2002; Shpiro et al. 2009). Dynamic inputs are linked to sensory features by mimicking the neuronal responses from electrophysiological recordings (awake macaque, A1) (Micheyl et al. 2005). Based on a conceptual description proposed in Fishman et al. (2001), the model considers competition downstream of A1. It captures the switching statistics of bistable auditory perception for long stimulus presentations and their dependence on DF (Rankin et al. 2015). A governing principal for asymmetric input manipulations in binocular rivalry (Levelt's proposition II (Brascamp et al. 2015; Levelt 1968); generalized for several visual modalities in Moreno-Bote et al. (2010)) was shown to hold for auditory streaming. It was shown in new experiments that as DF is varied, the durations of the stronger percept (dominant for a larger proportion of time) are affected more than the durations of the weaker percept, as predicted by the model.

An extension of the work accounts for early bias to integration and buildup (Fig. 1e) (Rankin et al. 2017). Our model demonstrates that broader tonotopic responses in A1 before rapid adaptation on a timescale of 500 ms biases toward integration, while the slower timescale of buildup (~ 10 s) emerges from competition downstream. It is the first treatment – through a direct link to observed neurophysiological responses – to explain both the initial bias for integration and the apparent disparity between adaptation timescales. The model can also account for new findings that while stimulus perturbations such as pauses are known to reset streaming to the integrated percept (Anstis and Saida 1985; Rogers and Bregman 1993), unexpected additional tones can promote the segregation of streams.

Other Neuronal Frameworks

In a modelling competition across a tonotopically organized feature space, Almonte et al. (Almonte et al. 2005) reproduced the van Noorden organization of perceptual bias. An advantage of this framework was the possibility to consider time-varying stimuli, which allowed for the crossing-bouncing illusion to be studied. Such a framework would be a good candidate to explore the time-varying stimuli used in van Noorden's experiments to determine the boundaries in terms of PR and DF for perceptual bias. Wang and Chang (2008) used an oscillator network and reproduced the van Noorden organization, but not the dynamics of buildup. The relatively abstract model includes a 2D array of oscillators across tone frequency and time (delay line) dimensions. This structure with significant redundancy is unlikely to be found in auditory brain regions.

Statistical and Bayesian Frameworks

The statistical properties of percept durations for auditory streaming share features across a range of bistable perceptual phenomena (Cao et al. 2016; Pressnitzer and Hupé 2006). Recent studies have shown that the distribution of perceptual durations is better described by a log-normal, rather than gamma (Pressnitzer and Hupé 2006), distribution (Rankin et al. 2015; Denham et al. 2018) (Fig. 1f). Two models based on probabilistic switching schemes (Barniv and Nelken 2015; Steele et al. 2015) can reproduce the characteristic distributions of perceptual durations. The statistical model of Steele et al. (2015), based on an alternating renewal process, reproduces the main features of buildup and alternations, but not observed switch time correlations. A dynamic Bayesian model for alternations using an evidence accumulation process (Barniv and Nelken 2015) succeeds in reproducing correlations. In these models the initial bias to integration is set by specifying a priori initial conditions (Barniv and Nelken 2015; Steele et al. 2015). A Bayesian inference framework has also been used to study streaming, focusing on the PR and DF dependence of

perceptual bias (Yates et al. 2017) and the crossing-bouncing illusion (Cusimano et al. 2018). A scaling property revealed in Cao et al. (2016) of the distribution of perceptual durations (constant ratio of the coefficient of variation and skewness) applies across a wide range of perceptually bistable phenomena, including auditory streaming. An abstracted statistical process can account for this property based on a finite birth-death process accumulating toward a threshold; however, this has yet to be captured in a model specific to auditory streaming (or any other bistable stimulus).

Discussion

Many of the modelling studies described here were successful in reproducing the characteristics of perceptual bias described by the van Noorden organization (Fig. 1C) (Almonte et al. 2005; Elhilali and Shamma 2008; Wang and Chang 2008; Yates et al. 2017). However, comparisons with van Noorden are often made without taking into account three important aspects of the original experiments: (1) time-varying stimuli, (2) attentional effects (e.g., instruction to “hold integration”), and (3) the termination of trials at the first perceptual switch. While some models account for the dynamics of buildup, e.g., Beauvois and Meddis (1991) and McCabe and Denham (1996), they ignore the fact that buildup accumulates after 5–10 s toward the steady-state probability of segregation for bistable alternations (Fig. 1d and e). More recently, models have focused on understanding these bistable alternations (Rankin et al. 2015; Steele et al. 2015) and, in some cases, account for buildup (Barniv and Nelken 2015; Mill et al. 2013; Rankin et al. 2017). While (Rankin et al. 2015, 2017) successfully bridged between available neurophysiological data from macaque A1 (Fishman et al. 2001; Micheyl et al. 2005) and behavior in humans (Pressnitzer and Hupé 2006), future insights are likely to be informed by a closer link to imaging work in humans (say, related to the effects of attention (Billig et al. 2018; Costa-Faidella et al. 2017; Kondo et al. 2018)), as yet unexplored in

models). For example, the importance of attention for binocular rivalry has been explored with imaging (EEG) (Zhang et al. 2011) and successfully modelled in a divisive normalization framework incorporating neuronal competition mechanisms (Li et al. 2017). Elsewhere, a recent model of beat perception (Large et al. 2015) is geared toward comparisons with and informative for imaging experiments (Tal et al. 2017). The next generation of models should make predictions testable with imaging experiments and focus on complex, dynamic stimuli approaching real-world situations.

Funding Rankin acknowledges support from an Engineering and Physical Sciences Research Council (EPSRC) New Investigator Award (EP/R03124X/1) and from the EPSRC Centre for Predictive Modelling in Healthcare (EP/N014391/1). This is a review study, and as such did not generate any new data.

Computational Models of Deep Brain Stimulation (DBS)

Jonathan E. Rubin¹ and Cameron McIntyre²

²Departments of Biomedical Engineering, Neurology, and Neurosurgery, Case Western Reserve University School of Medicine, Cleveland, OH, USA

Definition

DBS is a procedure in which a device is implanted within the brain and used to deliver pulses of electrical activity to the surrounding tissue. While parts of the device may extend elsewhere, the electrical stimulation is delivered in the interior of the brain, rather than outside of it or on its surface. Computational models of DBS are systems of equations representing some aspects of the DBS process, such as the electric field generated by a certain form of DBS or the predicted voltage responses of neurons impacted by this field, for which a computer can be used to obtain high accuracy approximate solutions. These predicted neural responses to DBS can then be introduced into network models of brain circuits, enabling theoretical investigation of the effects of DBS on brain activity.

Detailed Description

While DBS is being used or tested for use in treating a variety of conditions, computational models of DBS to date have primarily focused on DBS for Parkinson's disease (PD) and related states (collectively known as parkinsonism). Therefore, this review will focus on DBS models related to parkinsonism.

DBS for Parkinsonism

In DBS, a set of electrodes is surgically implanted into a brain area selected based on patient symptoms. The electrodes are linked to a subcutaneous

pulse generator outside of the brain, which causes electrical stimulation to be delivered through the electrodes with a prescribed frequency, amplitude, and timing. These stimulation parameters can be tuned externally to try to optimize the therapeutic results of DBS.

The mechanisms underlying the therapeutic efficacy of chronic high frequency (~100 Hz) brain stimulation remain mysterious and controversial. Recent research efforts have focused on the concept that disorders treated with DBS are fundamentally disorders of a specific brain network, as opposed to a specific neuron type, ion channel, or molecule (McIntyre and Hahn 2010). The basic working hypothesis is that DBS interacts with the diseased network to eliminate or subdue the underlying pathological neural activity (Rubin et al. 2012). Computational models have played an important role in the evolution of this hypothesis, suggesting that changes in the underlying dynamics of the stimulated brain networks may represent the core mechanisms of DBS and that those basic dynamical changes can be achieved via activation, inhibition, or lesion.

Computational Models of the Electric Field Associated with DBS for Parkinsonism

Computational modeling of DBS has established itself as a useful tool for investigating therapeutic mechanisms and designing techniques to optimize clinical application of DBS technology (McIntyre et al. 2007). A prime example comes from patient-specific DBS models, and the corresponding electric field generated by human DBS electrodes. The last decade has seen these models evolve from point source electrodes in an infinite homogeneous medium, to clinical electrodes in the human brain, to detailed representations of the electrode-tissue interface (Chaturvedi et al. 2010). The electric field predictions from modern DBS models have been validated against experimental measurements in the brains of nonhuman primates (Miocinovic et al. 2009) and electrophysiological measurements in human patients (Chaturvedi et al. 2010).

Patient-specific DBS models have had their greatest clinical impact in analysis of the target of the stimulation. In the case of subthalamic

nucleus (STN) DBS for PD, patient-specific models have demonstrated that activation of the white matter dorsal to the STN is most associated with therapeutic benefit (Maks et al. 2009; Butson et al. 2011). Further, when this region is explicitly targeted via surgical electrode placement (Plaha et al. 2006) or stimulation parameter selection (Frankemolle et al. 2010), outcomes improve relative to stimulation concentrated on the STN itself.

More recently, patient-specific DBS models have concentrated on the integration of connectomic data (models of structural or functional connectivity) into their stimulation analyses (Horn 2019). These models have highlighted to role of directly stimulating cortical connections to the deep brain surgical targets in the generation of therapeutic effects (Akram et al. 2017; Gunalan et al. 2017).

Computational Models Focusing on the Network Response to DBS for Parkinsonism

There are several different characteristics that can be used to classify those existing models that focus on the network response to DBS for parkinsonism. Computational models are generally motivated by an *underlying hypothesis for the central mechanism of DBS efficacy*, although such hypotheses need not be mutually exclusive. Depending on which hypothesis is under study, models may vary in their *mathematical formulations*, *level of abstraction of model neurons*, *selection of brain structures modeled*, and *representation of DBS inputs*.

For example, a common general hypothesis is that DBS works by eliminating pathological synchrony in basal ganglia structures. This idea can be explored using model equations representing many individual neurons or using models in which variables correspond to entire populations of neurons (e.g., one equation for each basal ganglia area). In the former approach, which allows the timing of individual neuron spikes to be considered, neurons have been represented as either abstract oscillators or as more biophysical units. In the latter approach, model equations can track phase density, with synchronization corresponding to a peaked phase distribution

(Tass 2002). Alternatively, the population approach can be based on firing rate or some other measure of net activity, which only allows for the analysis of synchrony between populations, not within a population. Similarly, both of these frameworks can be utilized to consider alternative hypotheses not emphasizing synchrony. They have been used, for example, to consider DBS-induced changes in burstiness (Rubin and Terman 2004; Modolo et al. 2008; Hahn and McIntyre 2010) or firing rates (Moroney et al. 2008; Humphries and Gurney 2012) within various basal ganglia nuclei. In particular, models have been used to consider the specific hypothesis that DBS can replace pathologically bursty and irregular firing with more regularized outputs. Some of these models include additional brain structures such as thalamic nuclei downstream from the basal ganglia, so that predictions can be made about the impact that altered basal ganglia firing patterns have on activity outside of basal ganglia (Rubin and Terman 2004), have considered effects of DBS applied directly to thalamic targets (Grill et al. 2004), or have included some form of cortical inputs (Hahn and McIntyre 2010). Finally, neurons need not be modeled explicitly at all; instead, they can be represented as stochastic processes yielding discrete spiking events, which may be useful for considering hypotheses about differences in correlations, information transfer, or signal propagation with and without DBS (Reitsma et al. 2011; Rosenbaum et al. 2014). One interesting idea is that DBS may eliminate pathological structure in basal ganglia outputs by inducing stochastic short-term depression (due to synaptic dynamics and axon failure), and this has been modeled using stochastic processes as well as single-compartment biophysical neuron models (Rosenbaum et al. 2014).

DBS inputs themselves are represented simply as applied currents within many computational models. These currents may be delivered at multiple sites, with various timings, or may be derived from computationally generated feedback signals (Hauptmann et al. 2005). Alternatively, a more involved field model of DBS may be coupled to a detailed neuronal model for consideration of

spatial effects (Yousif et al. 2012). Some computational modeling studies have circumvented the need for an explicit representation of DBS by incorporating experimentally recorded data from basal ganglia structures, collected with and without DBS, as inputs into a computational model (Guo et al. 2008; Dorval et al. 2008; Meijer et al. 2011; Cleary et al. 2013). Even without experimental recordings or modeling of DBS currents, DBS effects may also be included in a model through a phase resetting curve, which is a mathematical representation of how neurons respond to general inputs (Wilson et al. 2011), or through altered probability of spike generation in stochastic process models of neuronal circuits (Rosenbaum et al. 2014).

Computational Models of Mammalian Respiratory CPG

Jeffrey C. Smith

Cellular and Systems Neurobiology Section,
NINDS/NIH, Bethesda, MD, USA

Definition

Rhythmic breathing movements in mammals are produced by a central pattern generator (CPG), consisting of specialized neuronal networks located in the brainstem that are capable of endogenously producing patterned rhythmic activity. This activity emerges from the intrinsic biophysical properties and synaptic interconnections of spatially distributed neuron populations within the pontine–medullary circuits comprising the CPG. These circuits are embedded in a larger respiratory neural control system engaging various central nervous system (CNS) and peripheral afferent inputs that regulate the neural activity patterns including the oscillation period and amplitude of the output rhythmic motor activity to adjust it to the internal and/or external environment for sensorimotor integration and physiological homeostasis of O₂ and CO₂ in the body. Computational models of the brainstem respiratory CPG that incorporate various levels of biological and mathematical detail have been in development for several decades with the objective of explaining the dynamical operation of the CPG neurons and circuits, particularly to

delineate mechanisms of respiratory rhythm and pattern generation. Recent data-driven models that have explored functional architecture of the CPG circuits and advanced understanding of these mechanisms are reviewed.

Detailed Description

Respiratory Motor Patterns and CPG Activity: Neurophysiology

A major objective of the models described in this entry is to reproduce experimental data and provide mechanistic explanations for the activity patterns and operation of identified or postulated key components of the brainstem respiratory CPG and associated motor output patterns during the normal respiratory cycle. The basic activity patterns of brainstem–spinal neurons and efferent motor behaviors of the CPG to be explained have been established experimentally from electrophysiological recording studies (see Lindsey et al. 2012 for a comprehensive review). Essential neurophysiological features as they are presently understood that need to be taken into account in computational modeling analyses are summarized below.

During normal breathing in mammals, the rhythmic motor pattern consists of three neural activity epochs or “phases”: inspiration (I, phase 1), post-inspiration (post-I, phase 2), and the later second stage (called E-2) of expiration constituting phase 3 of the respiratory cycle (Richter and Smith 2014) (Fig. 1). This three-phase motor pattern is phylogenetically conserved in all mammalian species from rodents to humans and reflects the coordinated activity of numerous populations of brainstem and spinal motoneurons that are driven and controlled by the output of the brainstem CPG circuits. At the brainstem level, the cranial motoneurons control musculature of the upper airways (e.g., hypoglossal, glossopharyngeal, laryngeal muscles), and motoneurons at the spinal cord level innervate muscles of the respiratory pump (diaphragm, thoracic, abdominal musculature). This neural pattern is also reflected in the activity profiles of the antecedent interneuron populations (Fig. 1) in specific

anatomically defined regions of the medulla oblongata and pons generating the three-phasic rhythmic drive. That is, there are distinct populations of neurons that are predominantly active with some temporal dispersion during the inspiratory phase or during the post-I or later E-2 phase of expiration. This has been determined experimentally by extracellular recording and mapping of single neuron or neuron population activity, including with large arrays of microelectrodes enabling simultaneous recordings at multiple brainstem sites for temporal correlation of activity, allowing inferences about network connectivity to guide computational analyses of circuit interactions (Lindsey et al. 2012). There have also been numerous intracellular recording studies that reveal the spiking activity and underlying synaptic inputs or biophysical properties of the different neuron types, which are critical for conductance-based modeling analyses of neuronal circuit activity and neuronal interactions (Richter and Smith 2014).

Each phase of the respiratory cycle is functionally and behaviorally distinct. During inspiration, medullary inspiratory premotoneurons (i.e., bulbospinal neurons with direct monosynaptic connections to spinal motoneurons, see Fig. 2) drive the activity of phrenic motoneurons that control contraction of the diaphragm via the phrenic nerve (PN) to inflate the lungs. Medullary inspiratory neurons also drive cranial hypoglossal motoneurons (Fig. 2) to activate via hypoglossal nerves (HN) tongue protrussor muscles to prevent obstruction of the oropharyngeal airway during inspiration. Other cranial motoneurons with projecting axons in branches of the vagus nerve innervate laryngeal muscles that control abduction of the glottis and vocal cords to maintain upper airway patency. The post-I phase of motor output is evident in recordings from the recurrent laryngeal or central vagus nerves (cVN) (e.g., Richter and Smith 2014) and is essential for controlling musculature regulating the caliber of the upper airway during expiration as well as integrating breathing with several other orofacial motor behaviors including vocalization and swallowing. During this phase the larynx is initially partially adducted (closed), which stalls airflow to provide

Computational Models of Mammalian Respiratory CPG, Fig. 1 Patterns of neuronal population activity from extracellular recordings in the medulla and motor output patterns recorded from spinal (PN) and cranial nerves (central vagus, cVN, and hypoglossal, HN) during the three-phase respiratory cycle. Neuronal population recordings have been obtained in key structural–functional compartments (BötC, pre-BötC, and rVRG, refer to Fig. 2). Recordings were obtained from juvenile rat brainstem–spinal cord preparations and are integrated and averaged over multiple cycles to show relative timing and activity profiles during the three-phase cycle. The active

inspiratory (I) and expiratory (E) neurons are typically classified with nomenclature based on profiles of their firing patterns (e.g., decrementing, augmenting spiking frequency) and their predominant activity phase. As depicted, pre-I/I neurons in the pre-BötC start firing before and continue into inspiration; early-I neurons have peak spiking in early-I followed by a decrementing pattern; rVRG aug-I neurons have an augmenting (also called ramping) firing pattern; post-I neurons, a decrementing firing pattern; and aug-E neurons, an augmenting firing pattern during E-2 (After Smith et al. 2009)

more time for gas exchange, and then slowly abducted (opened) to allow exhalation. In the premotor network producing this activity (Fig. 1), this phase is also critical for dynamically off-switching inspiration in the core microcircuits. During the E-2 phase of expiration, the active medullary expiratory bulbospinal neurons drive spinal thoracic and lumbar motoneurons (Fig. 1) to produce low levels of intercostal and abdominal muscle activity during normal (quiet) breathing. At higher levels of respiratory motor activity, such as when levels of carbon dioxide (CO_2) are elevated or levels of oxygen (O_2) are reduced, forced or active exhalation occurs during this phase,

which engages new circuit elements (Abdala et al. 2009; Rubin et al. 2011).

CPG Network Architecture and Circuit Components

Respiratory CPG circuits like all other GPG (and CNS) circuits are constructed from core sets of interacting excitatory (glutamatergic) and inhibitory (glycinergic and/or GABAergic) populations of interneurons whose activity is transmitted via mono- and polysynaptic circuits to motoneurons. The critical populations and their circuit

transmission circuits in the rVRG. BötC excitatory post-I neurons generate the post-I phase activity transmitted to cranial vagal motoneurons (I/E Mns, *brown*), which also receive inspiratory inputs from excitatory pre-BötC and rVRG neurons. The pre-I/I excitatory neurons of the pre-BötC are the excitatory “kernel” circuit neurons that project via premotor circuits to cranial motoneurons including hypoglossal and vagal motoneurons (*brown*) and to rVRG excitatory aug-I bulbospinal premotor neurons with projections to spinal cord inspiratory phrenic motoneurons (IMn, *brown*). Excitatory bulbospinal aug-E expiratory neurons of cVRG and driven by BötC aug-E excitatory neurons project to thoracic intercostal (IC) and abdominal (Abd) spinal expiratory motoneurons (EMns). Circuit neurons within these compartments receive tonic and in some cases phasic/rhythmic excitatory drive from the pontine, RTN/pFRG, and raphé compartments, where the latter two drives are in part chemosensory signals dependent on the blood/brain CO₂ level. Additional descriptions of the roles of the different populations of excitatory and inhibitory respiratory neurons are in the main text (After Smith et al. 2009)

populations to produce appropriately coordinated circuit activity and motor output patterns.

A central hypothesis in the respiratory neurobiology field is that these key populations of interneurons, which constitute the neural machinery for generating the three phases of the respiratory cycle, are bilaterally distributed in three anatomically defined and functionally distinct

compartments in the ventrolateral medulla (Fig. 2): the so-called Bötzing complex (BötC), pre-Bötzing complex (pre-BötC), and rostral ventral respiratory group (rVRG), which collectively are components of a more extensive rostro-caudally distributed “ventral respiratory column” (VRC) on each side of the brainstem (Smith et al. 2013; Fig. 2). Electrophysiological recording studies have shown that major populations of inspiratory neurons are concentrated in the pre-BötC (pre-I/I and early-I neurons, see Fig. 1 for nomenclature) and rVRG (aug-I neurons), while populations of expiratory neurons are in the BötC (post-I neurons, aug-E neurons active during the E-2 phase) and more caudally in the cVRG (aug-E). This spatial segregation of neuron types, although not exclusive, suggests a specific compartmental organization of mechanisms producing inspiratory and expiratory activity and that these populations form microcircuits that interact within and between these compartments. These microcircuits, depicted in Figs. 2 and 3, are postulated to represent key neural building blocks of the CPG network (Smith et al. 2007, 2013).

Experimental results also suggest that (1) the BötC contains neuronal machinery essential for generating expiratory activity, including populations of inhibitory neurons active during the post-I and E-2 expiratory phases; (2) the pre-BötC, a critical CPG component, has excitatory circuits that constitute the kernel inspiratory oscillator, these neurons have local intrinsic mechanisms for inspiratory rhythm generation, and there are also pre-BötC inhibitory interneurons driven locally by the excitatory neurons and are thus also active during inspiration; (3) the rVRG contains the main population of excitatory premotor bulbospinal inspiratory neurons that are driven by pre-BötC rhythmogenic excitatory neurons and project to phrenic motoneurons as well as cranial motoneurons so that activity of this population produces phrenic nerve (PN) inspiratory motor output and the inspiratory activity of cranial nerves (e.g., the laryngeal nerve innervating the upper airway); (4) generation of the normal three-phase respiratory pattern requires pontine circuits in the rostral brainstem, specifically excitatory

inputs to more caudal compartments especially the BötC to control generation of the post-I activity phase; and (5) other excitatory inputs such as from the retrotrapezoid nucleus or parafacial respiratory group (RTN/pFRG) in the more rostral medulla, which is a major source of chemosensory (CO_2/pH and O_2 -related) afferent input for homeostatic respiratory regulation, adaptively adjust the core CPG circuit activity in response to various metabolic demands. Other brainstem sources of afferent input are from the serotonergic raphé nuclei (also with CO_2 chemosensory properties, Fig. 2) and the nuclei of the tractus solitarius (NTS), which also project to the RTN and pons conveying mechanosensory signals and input from peripheral chemoreceptors (sensing O_2) (Smith et al. 2013).

Based on this spatial and functional organization, the current neurophysiological concept is that the respiratory rhythm and normal three-phase inspiratory–expiratory pattern emerge from circuit-based dynamic interactions between (1) the inhibitory neuronal populations in the BötC that are active during expiration, (2) the inhibitory neuron populations in the pre-BötC active during inspiration, and (3) the excitatory populations in the pre-BötC and rVRG that generate inspiration. The operation of this circuitry is controlled in part by other compartmentalized network components located in the more rostral medulla and pons that provide neural input “drives,” regulating dynamic behavior of the core CPG circuitry. The compartmental network organization is thought to be a basic design principle allowing flexible multilevel control of different circuit components for regulation of inspiratory and expiratory phase activity (Smith et al. 2013), giving rise to a repertoire of respiratory motor behaviors. The recent models described below attempt to computationally represent these processes.

Recent Computational Models: Overview

A basic problem in understanding the operation of the postulated core CPG circuits described above

Computational Models of Mammalian Respiratory CPG, Fig. 3 Circuit configuration of the conductance-based neuronal population model, incorporating the core mutual inhibitory ring-like structure within pre-BötC–BötC microcircuits and the inspiratory pre-BötC excitatory kernel circuits composed of pre-I/I spiking neurons with I_{NaP} functioning as an important conductance mechanism. Each neuronal component is represented in the model by a population of neurons. In the model simulations, all of these circuit components received tonic

excitatory synaptic drive from the sources depicted. Representative simulated integrated activities of the main populations of BötC, pre-BötC, and rVRG during the three-phase respiratory cycle are illustrated at the bottom. Integrated population activities are total number of spikes per sec/number of neurons ($n = 50$ neurons per population). Detailed descriptions of the model components and their interactions are in the main text (From Smith et al. 2009)

is to define how the intrinsic biophysical/electrophysiological properties of the constituent neuron populations, and population connectivity/synaptic interactions within specific circuit architectures, generate the spatiotemporal patterns of neuronal activity required for the three-phase organization of the respiratory motor pattern. Computational models of the brainstem respiratory CPG that incorporate various levels of biological and

mathematical detail have been in development for decades, exploring various facets of the dynamical operation of the GPG neurons and circuits. For a comprehensive review including historical perspectives, see Lindsey et al. (2012). Two types of recent models are described below – conductance-based and activity-based models of CPG circuits. These models incorporate the most recent experimental information on the structural–

functional organization of pontine–medullary network components (Fig. 2), as identified from neuroanatomical reconstruction or electrophysiological connectivity studies, and key biophysical/electrophysiological properties inferred from neuronal recording studies. The models represent at different levels of complexity how the inhibitory and excitatory network interactions and intrinsic biophysical mechanisms within the core circuitry, operating under control by external excitatory inputs such as from RTN/pFRG and the pons, contribute to rhythmic pattern generation in different network states. In addition to explaining circuit dynamics generating the normal three-phase respiratory pattern, these models have explored a number of other dynamical features of CPG operation. This includes rhythmogenic mechanisms embedded within the interacting pontine–medullary circuits that generate different experimentally observed motor patterns underlying distinct (patho)physiological respiratory behaviors (see Lindsey et al. 2012; Smith et al. 2013 for recent reviews).

Conductance-Based Computational Models

The conductance-based models developed by Rybak et al. (2007), Smith et al. (2007), and Rybak and Smith (2009) are extensions of their earlier models that incorporate synaptically coupled populations of inspiratory and expiratory spiking single-compartment neurons with biophysical properties and ion channel kinetics of membrane currents/conductances modeled in the Hodgkin–Huxley style. These model formulations incorporate experimentally characterized or postulated biophysical properties for respiratory neurons. The model neurons are assembled into individual populations for each functional type of inspiratory or expiratory neuron with heterogeneity of neurons built into individual populations by random distributions of some neuronal biophysical parameters and simulation conditions. Excitatory or inhibitory synaptic interactions among populations are modeled by incorporating

postsynaptic conductances in target neurons that are activated by spiking of neurons providing the activity-dependent synaptic inputs. The model circuitry, shown schematically in Fig. 3, also includes the tonically spiking neurons representing those identified electrophysiologically in the pons, RTN, and raphé nuclei that provide excitatory synaptic drive to the postulated microcircuits in the three major medullary compartments (BötC, pre-BötC, and rVRG) as described below.

The BötC compartment model microcircuit contains two populations of rhythmically active inhibitory expiratory neurons, the post-inspiratory (post-I) and the augmenting expiratory (aug-E) neurons active during the E-2 phase. These populations inhibit neuronal populations within the pre-BötC and rVRG and reciprocally inhibit each other (Fig. 2). The BötC compartment contains an excitatory post-I population (post-I(e)) that contributes to the simulated central vagus (cVN) cranial motor output. All BötC neurons have intrinsic spike frequency adaptation properties defined by a high-voltage-activated calcium (I_{CaL}) with calcium flux activating calcium-dependent potassium currents ($I_{K,Ca}$, see Eq. 2 below).

The pre-BötC compartment in the model includes two rhythmically active inspiratory neuronal populations: pre-I/I and early-I(1) (Figs. 1 and 2), where the pre-I/I population is the key excitatory population of pre-BötC serving as a major source of network inspiratory activity. This population projects to the aug-I population of premotor inspiratory neurons of the rVRG and via an excitatory hypoglossal premotor neuronal population to the hypoglossal motor output (HN) (see Fig. 2; not shown in Fig. 3). Motoneuron populations are not explicitly incorporated in the model, and the activity of premotoneuron populations is considered to be representative of motor outputs since the activity patterns of motoneurons have been shown electrophysiologically to generally follow the activity of premotoneurons providing excitatory monosynaptic inputs. The pre-I/I populations of excitatory neurons, which are synaptically coupled by mutual excitatory

connections, play a critical role in generating the inspiratory rhythm. In the model, as found experimentally, some of these cells have intrinsic oscillatory bursting properties dependent on a persistent sodium current (I_{NaP}) – an experimentally established conductance mechanism underlying membrane voltage-dependent intrinsic rhythmogenic behavior of pre-BötC circuits in which endogenous oscillatory bursting is a function of the level of neuronal excitability or tonic excitatory drive (Smith et al. 2007; Richter and Smith 2014). All pre-BötC excitatory neurons in this model have I_{NaP} . Earlier conductance-based models of I_{NaP} -dependent bursting in a network model of isolated pre-BötC excitatory circuits (Butera et al. 1999a, b; see also Butera et al. 2005 for review) have shown that an increase in the average neuronal excitability or in external excitatory drive increases the inspiratory burst frequency over a large dynamic range (Purvis et al. 2007) and ultimately switches population activity to a mode of tonic asynchronous spiking. In the CPG model, where the pre-BötC circuits are embedded in the larger network providing inhibitory and excitatory inputs, under normal conditions, most neurons of the pre-BötC excitatory population are assumed to operate in a tonic-spiking mode due to high tonic excitatory input and are phasically inhibited by the expiratory neurons (post-I, aug-E) (discussed in Smith et al. 2007).

The early-I(1) population within the pre-BötC compartment is a population of inhibitory interneurons with adapting properties (also governed by I_{CaL} and $I_{K,Ca}$) and receives excitation from the pre-I/I population. In the modeled network, this population serves as a major source of inhibition of all expiratory neurons during inspiration (see Fig. 2).

Thus an important circuit architectural feature of this model is that the minimal core structure of the CPG is represented by BötC inhibitory expiratory (post-I and aug-E) neurons and the inhibitory inspiratory neurons in the pre-BötC, coupled in a ring-like network with mutual inhibitory interactions (Fig. 3). This inhibitory network interacts with the key excitatory kernel network

of pre-BötC inspiratory neurons to coordinate the generation of inspiratory and expiratory activity patterns. In this model synaptic inhibition is essential for orchestrating phase transitions to generate the three-phase respiratory pattern.

The rVRG compartment contains the aug-I excitatory, and early-I(2) inhibitory, populations. Aug-I represents the rhythmically active population of premotor inspiratory neurons projecting to and exciting phrenic motoneurons. Activity of this population in the model represents PN output and contributes to the inspiratory component of cVN discharge. The role of the inhibitory early-I (2) population of adapting neurons in the model is in shaping the ramping patterns of aug-I neurons. The tonic excitatory drives to these neurons contribute importantly to the augmenting activity pattern.

Single Model Neuron Conductance Descriptions and Population Modeling: Mathematical Formulations

Neurons in this model are represented as single-compartment cells with ionic currents for membrane channels described following the classic Hodgkin–Huxley formulation as summarized below, following closely the description given in the original papers (Rybak et al. 2007; Smith et al. 2007). The simplified ionic current (I) equation for the pre-BötC excitatory neurons is

$$C \cdot \frac{dV}{dt} = -I_{Na} - I_{NaP} - I_K - I_L - I_{SynE} - I_{Syn} \quad (1)$$

and the early-I (1, 2), aug-I, post-I, and aug-E neurons are modeled by

$$C \cdot \frac{dV}{dt} = -I_{Na} - I_K - I_{CaL} - I_{KCa} - I_L - I_{SynE} - I_{Syn} \quad (2)$$

where V is the membrane potential, C is the membrane capacitance, and t is time. The ionic currents represented on the right side of these current

balance equations are I_{Na} [fast (transient) sodium current], I_{NaP} [persistent (slow inactivating) sodium current], I_K (delayed rectifier potassium current), I_{CaL} (high-voltage-activated calcium-L current), I_{KCa} (calcium-dependent potassium current), I_L (leakage current), and I_{SynE} and I_{SynI} (excitatory and inhibitory synaptic currents, respectively). Expressions for individual currents are as follows:

$$\begin{aligned} I_{Na} &= g_{Na} \cdot m_{Na}^3 \cdot h_{Na} \cdot (V - E_{Na}); \\ I_{NaP} &= g_{NaP} \cdot m_{NaP} \cdot h_{NaP} \cdot (V - E_{Na}); \\ I_K &= g \cdot m_K^4 \cdot (V - E_K); \\ I_{CaL} &= g_{CaL} \cdot m_{CaL} \cdot h_{CaL} \cdot (V - E_{Ca}); \\ I_{KCa} &= g_{KCa} \cdot m_{KCa}^2 \cdot (V - E_K); \\ I_L &= g_L \cdot (V - E_L); \\ I_{SynE} &= g_{SynE} \cdot (V - E_{SynE}); \\ I_{SynI} &= g_{SynI} \cdot (V - E_{SynI}), \end{aligned} \quad (3)$$

where E_{Na} , E_K , E_{Ca} , E_L , E_{SynE} , and E_{SynI} are the reversal potentials and g_{Na} , g_{NaP} , g_K , g_{CaL} , and g_{KCa} are maximum conductances of the corresponding channels; g_{SynE} and g_{SynI} are excitatory and inhibitory synaptic conductances, respectively, and g_L is the constant leak conductance.

The kinetics of the activation and inactivation gating variables m_i and h_i (indexes indicate individual ionic currents), respectively, are described as

$$\begin{aligned} \tau_{mi}(V) \cdot \frac{d}{dt} m_i &= m_{\infty i}(V) - m_i; \\ \tau_{hi}(V) \cdot \frac{d}{dt} h_i &= h_{\infty i}(V) - h_i. \end{aligned} \quad (4)$$

The expressions for steady-state activation and inactivation variables, time constants, value of maximal conductances for individual neuron types, and the sources of experimental data from which model parameters were obtained are presented in the original papers (Rybak et al. 2007; Smith et al. 2007).

For currents gated by the internal calcium concentration in the model (I_{KCa}), the kinetics of intracellular calcium concentration Ca is described as follows:

$$\begin{aligned} \frac{d}{dt} Ca &= -k_{Ca} \cdot I_{CaL} \cdot (1 - P_B) \\ &+ (Ca_0 - Ca)/\tau_{Ca} \end{aligned} \quad (5)$$

where the first term constitutes influx (with the coefficient k_{Ca}) and buffering (with the probability P_B) such that $P_B = B/(Ca + B + K)$, where B is the total buffer concentration and K is the rate parameter. The second term describes kinetics of a calcium pump with resting level of calcium concentration Ca_0 and time constant τ_{Ca} . The calcium reversal potential in the model is a function of Ca :

$$E_{Ca} = 13.27 \cdot \ln(4/Ca) \text{ (at rest } Ca = Ca_0 = 5 \cdot 10^{-5} \text{ mM and } E_{Ca} = 150 \text{ mV)} \quad (6)$$

For modeling multiple neuronal populations and their synaptic interactions, each functional type of neuron (pre-I/I, early-I, post-I, aug-E) is represented by a population of 50 neurons. Connections between populations in this model are specified so that if a population A was assigned to receive an excitatory or inhibitory input from a population B or external excitatory drive d , then

each neuron of population A received the corresponding excitatory or inhibitory synaptic input from each neuron of population B or from d , respectively. The excitatory (g_{SynE}) and inhibitory postsynaptic (g_{SynI}) conductances are activated by the network activity-dependent excitatory or inhibitory inputs, respectively, formulated as

$$\begin{aligned} g_{SynEi}(t) &= g_E \cdot \sum_j S\{w_{ji}\} \cdot \sum_{t_{kj} < t} \exp(-(t - t_{kj})/\tau_{SynE}) + g_{Ed} \cdot \sum_m S\{w_{dmi}\} \cdot d_{mi} \\ g_{SynIi}(t) &= g_I \cdot \sum_j S\{-w_{ji}\} \cdot \sum_{t_{kj} < t} \exp(-(t - t_{kj})/\tau_{SynI}) + g_{Id} \cdot \sum_m S\{-w_{dmi}\} \cdot d_n \end{aligned} \quad (7)$$

where the function $S\{x\} = x$, if $x \geq 0$, and 0 if $x < 0$. The first terms in the above two Eq. 7 describe the dynamics of integrated synaptic inputs from other network neurons. The second term describes the integrated inputs from external drives d_{mi} . The activity dependence of these inputs is handled by considering that each action potential arriving to neuron i from neuron j at time t_{kj} increases the excitatory synaptic conductance by $g_E \cdot w_{ji}$ if the synaptic weight $w_{ji} > 0$ or increases the inhibitory postsynaptic conductance by $g_I \cdot w_{ji}$ if the synaptic weight $w_{ji} < 0$. The parameters g_E and g_I define the increase in the excitatory or inhibitory synaptic conductance, respectively, produced by one action potential arriving for $|w_{ji}| = 1$, and t_{SynE} and t_{SynI} represent the decay time constants for the excitatory and inhibitory conductances, respectively. In the second term of Eq. 7, the parameters g_{Ed} and g_{Id} define the increase in excitatory or inhibitory postsynaptic conductance, respectively, produced by external input drive $d_{mi} = 1$ with a synaptic weight of $|w_{dmi}| = 1$. In the original model, $g_{Id} = 0$. The relative weights of synaptic connections (w_{ji} and w_{dmi}) during the three-phase operation and other states of the network are provided in the original publications. Heterogeneity of neurons to account for biological variability within each model population was incorporated by a random distribution of E_L (mean values $\pm$ SD) as well as the initial conditions for values of membrane potential, calcium concentrations, and channel conductances.

Dynamical Operation of Model Core Circuitry

Examples of the simulated output of this model are shown in Figs. 3 and 4, which illustrate neuron population activity patterns (Fig. 3) and the membrane potential trajectories (Fig. 4) including spiking patterns and the temporal profiles of postsynaptic inhibitory conductances in single representative neurons from each of the four main neuron populations in the pre-BötC and BötC circuitry. The integrated population activities are comparable to electrophysiological recordings (Fig. 1) obtained from an experimental preparation (in situ perfused brainstem–spinal

cord preparation from juvenile rat) (Smith et al. 2007, 2009), which spontaneously generates the three-phase respiratory pattern that is recorded at the neuron population level in medullary compartments and from cranial and spinal nerves monitoring motor output. The model parameters chosen and model simulations were designed to reproduce experimental data obtained from this preparation (see Smith et al. 2007 for details). The simulations have reproduced some essential temporal features of the three-phase organization of the neuron population activities and network outputs. This correspondence has been interpreted to imply that the minimal architecture for the core pre-BötC and BötC circuits represented in the model defines essential excitatory and inhibitory population interactions for generating the three-phase rhythmic pattern. In additional tests of this model, simulations could mimic a number of experimental observations including results from experiments examining (1) pharmacological perturbations of the cycle frequency and amplitude of population activity by blocking I_{NaP} , (2) disruptions of network activity by reducing inhibitory synaptic conductances, and (3) transformations of CPG network activity, motor patterns, and underlying rhythmogenic mechanisms as the network was physically reduced and functionally reconfigured. Regarding the latter, this model has delineated mechanistically how the core CPG components could be built hierarchically by assembling the postulated local pre-BötC and BötC microcircuits with their particular electrophysiological properties and their regulation by external excitatory drive inputs. Thus the model has shown that this type of circuit assembly has the capability for functional reorganization under different (patho)physiological conditions, which is considered an important property of the CPG.

The membrane trajectories and postsynaptic inhibitory conductances from representative single model neurons (Fig. 4) serve to illustrate in principle the dynamical operation of the core rhythmogenic microcircuits, particularly how the mutual inhibitory interactions within the ring-like architecture of circuit connections can orchestrate phase transitions to produce the three-phase respiratory pattern. Sequential events (numbered in the figure) beginning with the inspiratory (I) period

Computational Models of Mammalian Respiratory CPG, Fig. 4 Simulated membrane potential trajectories and time courses of inhibitory postsynaptic conductances in single neurons from the four major populations of the core pre-BötC and BötC circuitry in the conductance-based model with connections as depicted in Fig. 3. Sequential events beginning with the inspiratory (I) period are numbered and correspond to the stepwise

description given in the text, which provides an explanation of the dynamical operation of these microcircuits. This explanation emphasizes the roles of synaptic inhibition and intrinsic cellular biophysical properties in orchestrating phase transitions and neuronal rhythmic activity patterns underlying generation of the three-phase respiratory pattern (The figure is from Smith et al. 2013 with permissions)

are as follows. **(1)** During the inspiratory phase, activity of the pre-BötC early-I inhibitory population declines due in part to intrinsic spike frequency adaptation. This enables slow disinhibition of the BötC post-I neurons, evident in the trajectory of the post-I neuron inhibitory conductance **(2)**. Spiking of post-I inhibitory neurons **(3)** initiates inhibition of inspiratory activity by the abrupt rise of inhibitory conductance in pre-I/I **(4)** and early-I neurons, terminating the inspiratory phase. Simultaneous inhibition of BötC aug-E neurons **(5)** with the rapid onset of

inhibitory postsynaptic conductance also silences these neurons. Activity of the aug-E neuron population **(6)** is disinhibited and develops later in expiration, forming the second expiratory (E-2) phase, as the post-I neuron spiking frequency declines (adaptation). Aug-E neuron activity causes inhibitory conductance in post-I neurons to further reduce their spike frequency **(7)**, while the simultaneous inhibition of early-I neurons **(8)** transiently prevents reactivation of these neurons. The pre-I/I neurons in pre-BötC are only weakly inhibited in the model during the E-2

phase and receive high tonic excitatory drive, which in combination with the recovery from I_{NaP} inactivation in these cells enables escape from inhibition and onset of pre-inspiratory phase spiking activity (9) initiating a wave of synaptic excitation in the network. The resultant strong excitation to the early-I inhibitory neurons and their rapid onset of spiking (10) initiates strong inhibition of post-I and aug-E neurons, completing the E-to-I transition and initiation of the next cycle. These model-based descriptions for the generation of the three-phase respiratory pattern are generally in accord with classical descriptions of Richter and colleagues, but in the current model, involvement of specific compartmental microcircuits and their more recently elaborated electrophysiological properties are considered (see Richter and Smith 2014 for recent review).

Some Model Limitations

This model, as noted above, is a highly simplified representation of microcircuits within the CPG that attempts to define key features of the architecture and dynamics of postulated core circuitry incorporating simplified sets of neuronal biophysical properties. A key feature of the model is the asymmetric strengths of mutual synaptic interactions within the ring-like inhibitory connectome. In combination with strong intrinsic spike frequency adaptation properties of two of the inhibitory populations (post-I and early-I), this connectome enables the orderly progression of the cycle activity phases. Such asymmetry has not yet been examined and verified experimentally. Furthermore, all neurons in this model are assumed to receive tonic excitation that facilitates the phase transitions. The mapping of excitatory input drives onto the circuitry and the relative strengths of drives have also not been analyzed and confirmed experimentally. Some of the inputs from the sources represented in the model may in fact be rhythmic, and some models have attempted to explicitly incorporate state-dependent phasic inputs (Rubin et al. 2011; Lindsey et al. 2012). The interacting processes

leading to stable transitions between each activity phase are dynamically complex (see section “Activity-Based Computational Models” below), and the processes operating in the real network are undoubtedly not fully represented in the model. As shown from electrophysiological recordings, the three phases of the cycle are not strictly sequential with some temporal overlap, reflected by the spiking activity profiles of population neurons, particularly subsets of post-I neurons that spike into the E-2 phase, and pre-I/I neurons that begin spiking in the E-2 phase. These features are present in the model simulations. However, there is also temporal dispersion in the spiking patterns of different neurons within a population active during a given phase. For example, it has been established experimentally that there are also expiratory neurons with spiking confined primarily to the post-I phase. Currently it is not clear whether this reflects heterogeneity of synaptic inputs and/or electrophysiological properties within a given neuronal population, which is a feature of the current model, or if this reflects functionally distinct subpopulations.

This model assumes that the essential circuit interactions generating the respiratory rhythm are distributed between the BötC and pre-BötC regions, which is consistent with current experimental information but not yet definitively established. The spatial segregation of neurons with particular spiking patterns is not exclusive. For example, post-I spiking neurons are also located in the pre-BötC, which may imply that some of the inhibitory circuit interactions leading to inspiratory phase termination occur locally within this compartment. Regardless of the particular spatial arrangements, the circuit motifs and dynamic processes inherent in the present model are a plausible solution to the general problem of identifying canonical circuit architecture and neuronal interactions for generating the three-phase activity pattern. The mutual inhibitory connectome appears to be an important architecture for orchestrating the three-phase rhythmic pattern. More complex architectures with distinct subpopulations of glycinergic and GABAergic inhibitory neurons and their postulated network

interactions, but retaining key features of the inhibitory circuit interactions represented by the model described here, have been explored (Shevtsova et al. 2011). For more biophysically complex conductance-based models of pre-BötC excitatory circuit neurons, incorporating additional sodium- and calcium-based mechanisms for inspiratory rhythm generation, see for example Jasinski et al. 2013.

Activity-Based Computational Models

Activity-based (non-spiking) models of the core pre-BötC–BötC circuitry that incorporate the essential spike frequency adaptation properties of inhibitory neurons and I_{NaP} -dependent intrinsic burst generation mechanisms of pre-BötC excitatory neurons in a more simplified format have been developed by Rubin et al. (2009, 2011). These models have been used for computational studies of circuit dynamics in various states, including during the three-phase rhythmic pattern generation state as well as structurally reduced states of the CPG network that are considered to be functionally important. Activity-based neural models (Ermentrout and Terman 2010) are an established general form of models and have particular utility for (1) testing if the dynamical processes operating as described by more complex conductance-based models, such as for the core circuitry of the respiratory CPG as described above, can be adequately represented by a more minimal construct within a dynamical system's analytical and computational framework – this could imply that the basic circuit architecture and the proposed key dynamical properties of circuit elements can be a robust representation of the essential dynamical processes that are not a function of parameter tuning in the very large, complex parameter sets of the conductance-based model – and (2) applying numerical methods including bifurcation analysis, phase plane analysis, and fast–slow variable decomposition methods to analyze dynamic mechanisms underlying transitions between respiratory phases. These approaches have also enabled analyses of how gradual

changes of excitatory drives to particular cells in the network can control oscillation period and phase durations, which is an important physiological problem. In addition, transitions to other oscillatory regimes, such as experimentally established two-phase and one-(active) phase rhythmic activity states underlying important respiratory motor behaviors might be explained more rigorously, as well as the emergence of intermediate activity patterns in transitions between rhythmic states that have been observed experimentally.

This model was constructed with the same spatially organized network architecture as the conductance-based model and correspondingly contains four neurons ($i \in \{1, 2, 3, 4\}$), representative of the same neuronal populations, and three sources of excitatory drive ($dk; k \in \{1, 2, 3\}$). The four neurons include one excitatory pre-I/I ($i = 1$) and one inhibitory early-I ($i = 2$) neuron, for these neuronal types in the pre-BötC as in the conductance-based model, and two inhibitory neurons, post-I ($i = 3$) and aug-E ($i = 4$), representing these populations in the BötC.

Each type of neuron in this model is described by the dependent variable V_i , which represents an average voltage for that (i -th) population, and each output $f(V_i)$ ($0 \leq f(V_i) \leq 1$) represents an averaged or integrated population activity at the corresponding average voltage. It is assumed that the dynamics of the average voltages can be represented in the model by a conductance-like analytical framework since regimes in which neurons within each population are synchronized are considered (Rubin et al. 2009). Thus, the model was formulated to also explicitly represent dynamics of ionic currents so that the role of I_{NaP} causing oscillatory activity and current causing neuronal adaptation properties could be incorporated. In essence, this is an interesting novel, hybrid form of activity-based models that is meant to capture some of the essential dynamics of conductance-based models.

Following closely the description given in Rubin et al. (2009), the membrane potential of the I_{NaP} -containing excitatory pre-I/I neuron, V_1 , is described by the differential equation:

$$C \cdot \frac{dV_1}{dt} = -I_{\text{NaP}} - I_K - I_{L1} - I_{\text{SynE}1} - I_{\text{SynI}1} \quad (8)$$

$$C \cdot \frac{dV_1}{dt} = -I_{\text{NaP}} - I_K - I_{L1} - I_{\text{SynE}1} - I_{\text{SynI}1} \quad (9)$$

The other three neuron types ($i \in \{2, 3, 4\}$) in the circuit explicitly have dynamic adaptation of the depolarized voltage trajectory defined by the outward potassium current I_{ADi} . Each of these neurons has a membrane potential V_i that evolves as

In the above equations, C is the neuronal capacitance, I_K represents the potassium delayed rectifier current, and I_{Li} ($i \in \{1, 2, 3, 4\}$) is the leakage current. $I_{\text{SynE}i}$ and $I_{\text{SynI}i}$ ($i \in \{1, 2, 3, 4\}$) are the excitatory and inhibitory synaptic currents, respectively, described by

$$\begin{aligned} I_{\text{NaP}} &= g_{\text{NaP}} \cdot m_{\text{NaP}} \cdot h_{\text{NaP}} \cdot (V_1 - E_{\text{Na}}), \\ I_K &= g_K \cdot m_K^4 \cdot (V_1 - E_K), \\ I_{ADi} &= g_{AD} \cdot m_{ADi} \cdot (V_i - E_K), \\ I_{Li} &= g_L \cdot (V_i - E_L), \\ I_{\text{SynE}i} &= g_{\text{SynE}} \cdot (V_i - E_{\text{SynE}}) \cdot \sum_{k=1}^3 c_{ki} \cdot d_k, \text{ for } i \neq 2, \text{ and} \\ I_{\text{SynE}2} &= g_{\text{SynE}} \cdot (V_2 - E_{\text{SynE}}) \cdot \left(a_{12} \cdot f_1(V_1) + \sum_{k=1}^3 c_{ki} \cdot d_k \right), \\ I_{\text{SynI}i} &= g_{\text{SynI}} \cdot (V_i - E_{\text{SynI}}) \cdot \sum_{\substack{j=2 \\ j \neq i}}^4 b_{ji} \cdot f_j(V_j). \end{aligned} \quad (10)$$

In these equations g_{NaP} , g_K , g_{AD} , g_L , g_{SynE} , and g_{SynI} are the maximum conductances of the corresponding currents and E_{Na} , E_K , E_L , E_{SynE} , and E_{SynI} are the corresponding reversal potentials; a_{12} defines the weight of the excitatory synaptic input from the pre-I/I to the early-I neuron (see Fig. 5); b_{ji} defines the weight of the inhibitory input from neuron j to neuron i ($i \in \{1, 2, 3, 4\}$, ($j \in \{2, 3, 4\}$); and c_{ki} defines the weight of the excitatory synaptic input to neuron i from drive k (d_k , $k \in \{1, 2, 3\}$). The asymmetries in synaptic weights for the mutual inhibitory interactions between early-I, post-I, and aug-E neurons (e.g., $b_{23} > b_{32}$, $b_{34} > b_{43}$, but $b_{24} = b_{42}$) specify the order in which these cell types generate action potentials to produce the three-phase rhythmic pattern. For the analysis of effects of total independent excitatory drives (D_i , $i \in \{1, 2, 3, 4\}$) to different target neurons, D_i were varied without decomposition into weighted sums of drives d_k . In

these cases, in the equations for $I_{\text{SynE}i}$ and $I_{\text{SynI}i}$ of the system (Eq. 10), the term $\sum_{k=1}^3 c_{ki} \cdot d_k$ was replaced in the model with D_i (see Fig. 5).

The output activity of each neuron type (indirectly representing the rate of spiking activity) is defined by the nonlinear function $f_i(V_i)$

$$f_i(V_i) = 1 / (1 + \exp(-(V_i - V_{1/2})/k_{Vi})), \quad i \in \{1, 2, 3, 4\} \quad (11)$$

where $V_{1/2}$ is the half-activity voltage and k_{Vi} defines the slope of the output function for each neuron.

The two slow variables in the model (h_{NaP}), representing the slow inactivation of I_{NaP} in neuron 1 (pre-I/I), and m_{ADi} ($i \in \{2, 3, 4\}$), defining the time course of adaptation in the other three

Computational Models of Mammalian Respiratory CPG, Fig. 5 Activity profiles of the four main types of neurons in the pre-BötC–BötC microcircuitry and control of respiratory cycle period and phase durations by tonic excitatory drives from simulations with the activity-based model of Rubin et al. (a) The distinct populations of inspiratory and expiratory neurons of the core circuitry within the BötC and pre-BötC compartments provide multiple nodes that may be targeted by external drives for control of cycle period and phase durations. (b) Simulations show activity profiles of each neuron type of the core circuitry producing a three-phase activity pattern with respiratory cycle period (T) and durations of

inspiration (T_I) and expiration (T_E) with $T = 2.5$ s, $T_I = 0.9$ s, and $T_E = 1.6$ s that are within the observed experimental range. The voltage trajectories show adaptation properties of post-I and early-I neurons, slow depolarizing drift in voltage of pre-I/I neurons, and augmenting activity profile of aug-E neurons. Compare the profiles with integrated population activities of the conductance-based model shown in Fig. 3. (c) Dynamic ranges of T , T_I , and T_E with changes in total drive selectively to each neuron type $D_1 \dots D_4$, where the excitatory postsynaptic input to each neuron has been weighted in proportion to the drive (Modified from Rubin et al. 2009)

neurons (each with fixed time constant τ_{ADi} and maximal adaptation), are defined by k_{ADi} :

$$\begin{aligned} \tau_{hNaP}(V_1) \cdot \frac{d}{dt} h_{NaP} &= h_{CoNaP}(V_1) - h_{NaP}, \\ \tau_{ADi} \cdot \frac{d}{dt} m_{ADi} &= k_{ADi} \cdot f_i(V_i) - m_{ADi}^* \end{aligned} \quad (12)$$

Voltage-dependent activation and inactivation variables and time constants for I_{NaP} (based on the I_{NaP} kinetic model of Butera et al. 1999a) and activation of I_K channels in the pre-I/I neuron are described as follows:

$$\begin{aligned} m_{NaP} &= 1 & (1 + \exp(-(V_1 + 40)/6)), \\ h_{\infty NaP} &= 1 & (1 + \exp((V_1 + 48)/6)), \\ \tau_{hNaP} &= \tau_{hNapmax} & \cosh((V_1 + 48)/12), \\ m_K &= 1 & (1 + \exp(-(V_1 + 29)/4)). \end{aligned} \quad (13)$$

Rubin et al. noted that at most points in the eight-dimensional phase space representing the eight variables of this model, the voltages $V_1, \dots, V_4$ evolve much faster than the inactivation variable h_{NaP} and the adaptation variables m_{ADi} ($i = 2, 3, 4$). Accordingly, the voltages represent the fast variables, and the system of differential equations for $V_1, \dots, V_4$ represent the fast subsystem. Equilibrium points of this subsystem occur where the right-hand sides of all equations in the fast subsystem are zero and typically form smooth equilibrium surfaces. These investigators accordingly used bifurcation analysis to identify fast subsystem equilibrium surfaces and phase transitional features by numerically tracking the fast subsystem equilibrium surfaces along which the fast system variables are relatively constant and detecting bifurcation curves, where solutions jump away (“fast jumps”) from each surface. Thus, they demonstrated how bifurcation diagrams (see Rubin et al. 2009) can be created by treating the variables h_{NaP} and m_{ADi} as fixed parameters and following curves of equilibrium points of the differential Eqs. 8 and 9 for the voltages $V_1, \dots, V_4$. They also demonstrated that

in certain cases, bifurcation curves could be generated by simultaneously varying two activation variables while holding the other two fixed, whereas in other cases, all four activation variables could be varied simultaneously along a one-dimensional curve in four-dimensional space. The dynamics of the model phase transitions, analyzed with this approach, yielded new insights into the operation of the circuit in different states.

Dynamical Operation During Three-Phase Rhythmic Pattern Generation: New Insights

The three-phasic operation of this activity model, as illustrated in Fig. 5, generates stable oscillations with period T , duration of inspiration T_I , and duration of expiration T_E , which, as the model was parameterized, are within the physiological ranges observed experimentally in the brainstem–spinal cord preparations of juvenile rats whose activity the model was intended to mimic (as with the conductance-based model). The voltage trajectories show characteristic slow adaptation properties of post-I and early-I neurons, depolarizing drift in voltage of pre-I/I neurons during the expiratory period due to slow recovery from inactivation of I_{NaP} , and the augmenting activity profile typical of aug-E neurons, all of which are comparable to the temporal profiles of integrated population activities in the conductance-based model (see Fig. 3). During the expiratory phases, the adapting (decrementing) activity of the post-I neuron, which is defined by the dynamic increase in its adaptation variable m_{AD3} (see Eqs. 9 and 12), causes a decline in inhibition from the post-I neuron that shapes the augmenting profile of aug-E neuron activity and produces slow depolarization of the pre-I/I and early-I neurons. Simultaneously, the pre-I/I neurons are depolarizing due to the slow recovery from inactivation of I_{NaP} (slow increase of h_{NaP} , Eq. 12) so that at some moment the pre-I neurons rapidly activate, providing excitation of the early-I neurons. This inhibits both post-I and

aug-E neurons, completing the switch from expiration to the inspiratory phase in accord with the conductance-based descriptions. The analysis indicates that the moment of pre-I/I activation occurs when the system reaches a bifurcation curve along the post-I/aug-E equilibrium surface, allowing the fast voltage variables to evolve quickly until they again reach an equilibrium surface, yielding a fast jump to the inspiratory phase.

During the inspiratory phase, according to this analysis, the system drifts near a new equilibrium surface, with its dynamics governed by Eq. 12. The early-I neuron, with its adapting activity, is defined by the dynamic increase in its adaptation variable m_{AD2} (Eqs. 9 and 12). The associated decline in inhibition from this neuron produces the slow depolarization of the post-I and aug-E neurons, and eventually, the system reaches another bifurcation curve, and a second fast jump occurs. Within this fast jump, the post-I neuron rapidly activates and inhibits both inspiratory neurons (pre-I/I and early-I) and the aug-E neuron initially, producing the inspiratory to expiratory phase transition. The model analysis indicates that this transition is always facilitated by *release* (as distinguished from *escape*), with m_{AD2} growing during inspiration.

As discussed above for the conductance-based model, it is important to emphasize that although the expiratory period can be conditionally subdivided into post-inspiratory (with a dominant post-I neuronal activity) and late E-2 expiratory (with reduced post-I and increasing aug-E activity) phases, as the model is constructed, there is no distinct switching between post-I and aug-E neuron activity phases in the so-called three-phase rhythmic pattern. Mathematically, there are only two fast jumps observed by bifurcation analysis, and accordingly the rhythmic pattern is not strictly three-phase, although functionally this is the case, leading these investigators to term the normal respiratory pattern as a “bio” three-phase rhythm. Nonetheless, in the model V_1 and V_2 are able to escape from this complex temporal pattern of expiratory phase inhibition for the transition to the inspiratory phase, as occurs naturally. A novel interesting result of the analysis is that with a higher excitatory drive to the network, the

early-I neurons can release from inhibition first and initiate the transition to the inspiratory phase. Thus this model in general has delineated possible contributions of escape and release mechanisms to various phase transitions during the cycle.

Results of these computational analyses have also generally suggested that the basic architecture and key properties of the core circuit neurons, as represented in both the simplified activity-based model with reduced parameter sets and the more complex conductance-based model, constitute a robust dynamical structure. The mutual inhibitory ring-like architecture interacting with the embedded excitatory kernel intrinsically gives rise to stable phase transitions. This bolsters the conclusion that this represents a plausible canonical circuit arrangement within the CPG for generation of the three-phase rhythmic pattern.

Control of Oscillation Period and Phase Durations in the Three-Phase Rhythm-Generating State

One important problem in respiratory neural control addressed with this model is to delineate mechanistically how the excitatory drives from various sources (signaling changes in physiological conditions) control the frequency and durations of inspiratory–expiratory phase activity. Rubin et al. (2009) noted that each of the inhibitory and excitatory populations of the pre-BötC–BötC circuitry potentially represent nodes for control of period and phase durations in the intact respiratory network. To theoretically investigate this control with the activity-based model, the effects of variations in the total excitatory drive D_i to each neuron on the oscillation T and on the durations of T_I and T_E have been analyzed. Some of the results are summarized in Fig. 5.

In general this model showed that variations in drive to the different network cells impact the inspiratory and expiratory phase durations, and the overall oscillatory period, differently with the model operating in the regime generating the three-phase pattern (Fig. 5). For example, increasing the drive to aug-E neurons lengthened T (reduced respiratory frequency) by ~ 2.5 times

by prolonging T_E and by a small increase in T_I . The prolongation of T_E results from a stronger aug-E inhibition of inspiratory neurons that necessitates a greater recovery from adaptation and inactivation before the inspiratory phase can initiate, causing a delay in the onset of this phase. In contrast elevated drive to post-I neurons slightly decreased T (increase frequency) as T_E becomes shorter because the additional drive to post-I leads to stronger inhibition on aug-E. The resulting weaker activation of aug-E leads to a net weaker inhibition of pre-I/I and early-I neurons, allowing a slightly earlier escape to initiate the inspiratory phase.

With the drive targeting neurons in the pre-BötC, the cycle period can be reduced and frequency increased by a factor of 4 from its initial value with increasing drive to the pre-I/I excitatory neurons. This occurs primarily by shortening T_E because the increase in drive to the pre-I/I neuron allows this neuron to escape from inhibition earlier. Increasing drive to the pre-BötC early-I inhibitory neurons can also reduce T by a factor of ~ 2 but by reducing T_I and shortening of T_E , which results from an earlier escape of the early-I neuron from inhibition and corresponding earlier switch to the inspiratory phase. Interestingly, as noted above, with a sufficient increase in drive, the early-I cell can replace the pre-I/I cell as the initiator of the transition to inspiration. Experimental manipulation of neuron excitability within the pre-BötC modulates respiratory cycle frequency over a substantial dynamic range and reinforces the basic concept that the pre-BötC is a key rhythmogenic structure. According to the modeling results, both the excitatory and inhibitory neuron populations in the pre-BötC can play a role and represent different mechanisms for control of respiratory frequency and phase durations. This new insight points to potentially distinct mechanisms at this level of the circuitry.

These modeling results illustrate in principle how the inspiratory and expiratory neuron populations can be distinct nodes for differential control of period and phase durations. As pointed out by Rubin et al. (2009), the significant changes in the oscillation period following changes in drives to particular neurons revealed by the

model are not typical for classical mutual inhibitory half-center models. Mathematically, the different effects on period observed relate in part to the asymmetry between decrementing and augmenting activity patterns in different cells. Phase transitions in the model occur via combinations of adaptation, release from inhibition, and recovery from adaptation (or from I_{NaP} inactivation in the pre-I/I neurons) that provides the escape mechanism. Importantly, the activity-based modeling approach allowed the simulated changes in phase durations and oscillation periods to be linked mathematically to the different balances of escape and release from inhibition and the contributions of neuronal spike frequency adaptation, all of which collectively underlie the phase transitions. Thus, the modeling results generally demonstrate how activity patterns of different cell types in the CPG (1) dictate the forms of the transition curves between phases and underlie the distinctive role each cell population plays in the phase transitions and (2) govern the effects that changes in excitatory drive have on the phase transition curves and overall respiratory activity pattern.

In other results from this theoretical analysis, it has been demonstrated that the different nodes in the circuitry can not only differentially provide control of oscillation period and phase durations but also can allow for control of the mode of rhythmic pattern generation by the external drives. The detailed treatment of this aspect is presented in Rubin et al. (2009). This analysis has generally reinforced the conclusion from the conductance-based model that the core CPG circuits appear to contain multiple functionally embedded oscillatory mechanisms, ranging from mutual inhibitory network-based interactions between pre-BötC and BötC circuits resembling classical inhibitory half-center type structures to conductance-based endogenous rhythmogenic mechanisms within the pre-BötC, with important physiological implications. Another important extension of this activity-based model has been the inclusion of an additional state-dependent oscillatory mechanism for homeostatic regulation, in the RTN/pFRG, that becomes active under conditions of high respiratory drive (i.e., by

elevated CO₂ in the system) and dynamically interacts with pre-BötC–BötC oscillator to produce forced expiration – a respiratory motor behavior distinct from the normal three-phase motor output that occurs at normal resting levels of CO₂. Again, the application of analytical methods from dynamical systems theory has elucidated possible mechanisms and dynamic synchronization of these oscillators. These computational studies are reviewed by Molkov in this volume.

Summary Perspectives

The brainstem respiratory CPG has provided unique opportunities to experimentally unravel how cellular and circuit properties are integrated in the mammalian CNS to produce rhythmic motor behavior. Some of the properties of key components of this CPG have been experimentally investigated in extraordinary detail, yet many aspects of neuronal and circuit structural–functional properties remain to be established (Smith et al. 2013). The data-driven computational modeling approaches described have been instrumental in exploring plausible canonical circuit architectures and the dynamical operation of postulated core microcircuits of the CPG. With the recent advent of new connectomics and optogenetics approaches for reconstructing circuit structure–function, increasingly more detailed experimental information will become available. As with all CNS circuits, CPG circuit dynamics cannot be easily intuited even when circuit organization has been definitively established. Many opportunities therefore exist for future concerted experimental and computational studies investigating the operation of this vital CPG.

Computational Models of Modulation of Oscillatory Dynamics

Pawel Andrzej Herman
Computational Biology, KTH Royal Institute of Technology, Stockholm, Sweden

Definition

The term refers to a wide range of spiking neural network models that not only exhibit oscillatory behavior but also simulate neural effects and/or processes underlying ongoing changes in the oscillatory dynamics. These changes in the oscillatory dynamics, often referred to as modulations, can be of different nature: (i) quantitative where the key parameters of oscillations, e.g., amplitude or dominant frequency, vary over the course of a simulation and/or (ii) qualitative where the oscillatory regime undergoes state transitions. Modulatory mechanisms that underlie changes in the oscillatory behavior of a model could also be of various origins ranging from an external stimulus, entraining input, and specific excitatory/inhibitory drive to simulated neuromodulation or attentional effects.

Detailed Description

Background and Scope

Oscillations constitute an inextricable aspect of neural dynamics. Their origins and underlying mechanisms at a cellular as well as population level have been under investigation using both experimental and theoretical approaches. The

importance of oscillatory effects in the brain can largely be explained by abundant biological evidence for their correlations with various aspects of cognition and behavior. In this light, task- or function-dependent modulations of oscillatory dynamics bear special relevance to understanding the mechanisms, role, and nature of this prevalent phenomenon manifested at different scales of neural system organization. Computational models that capture such modulatory effects and demonstrate their impact on the ongoing neural dynamics and/or elucidate their functional implications on a circuit or system level serve as a valuable tool in unraveling the mystery of oscillations. The emphasis is here on spiking neural network models that simulate biologically relevant processes involved in dynamical modulation of ongoing neural activity in the brain. In other words, experimental scenarios where the effect of static manipulations of model parameters on the emergent oscillatory dynamics is tested in independent simulations lie outside the definition of the term of computational models of modulations adopted here.

The most common manifestations of modulatory effects are quantitative changes in parameters of neural rhythms, such as amplitude or peak frequency, and qualitative shifts of the oscillatory regime including synchronization effects. There is a wide range of mechanisms exploited in computational models to simulate modulations of oscillations. For example, the transitions between different oscillatory states in a multi-stable model can be induced by an external stimulus (e.g., Battaglia and Hansel 2006; Börgers et al. 2008; Herman et al. 2013; Lundqvist 2013a, b) or endogenously controlled by intrinsic cellular or network dynamics (Herman et al. 2013). Alternatively, a periodic modulation of oscillations can be imposed by varying noise conditions or other changing sources in order to study implications of changes in oscillatory dynamics (Lundqvist et al. 2013a). From a functional perspective, modulation of oscillatory phenomena in computational models is commonly studied in the context of neuromodulatory (Destexhe et al. 1994; Liljenström and Hasselmo 1995; Li and Cleland 2013) and attentional effects (Börgers

et al. 2005, 2008; Buia and Tiesinga 2006; Gu and Liljenström 2007; Buehlmann and Deco 2008) as well as perceptual and working memory processes (Lundqvist et al. 2012, 2013a, b; Herman et al. 2013). Then, depending on the modeling context, simulated modulation is most often related to cortical or hippocampal dynamics.

Since gamma rhythm with the peak frequency above 20–30 Hz constitutes the most prevalent spectral component of activity of oscillatory spiking network models, it is worth recalling its origin (Buzsaki and Wang 2012). The key neural mechanism involved is slow and fast feedback inhibition on a network level (Brunel and Hakim 1999; Whittington et al. 2000) or feedback inhibition on a cellular level (adaptation and other slow hyperpolarizing activity-dependent currents, e.g., Rotstein et al. 2005; Lundqvist et al. 2006; Herman et al. 2013). The network-level feedback inhibition can be exhibited either between excitatory and inhibitory cells leading to gamma-like oscillations at around 30 Hz (Brunel and Hakim 1999; Whittington et al. 2000) or between inhibitory neurons resulting in faster oscillations at frequencies higher than 60 Hz. In vivo both types of interactions are likely to contribute to the broadband gamma (Ainsworth et al. 2011).

Stimulus- or State-Dependent Modulations of Oscillatory Dynamics

Neural computation theories assume that in the macroscale brain processes information depending on incoming stimuli and its current dynamical as well as functional state. In the same spirit, modulation of the dynamics exhibited by network models often results from an external input/stimulus they receive and/or some intrinsic endogenous state transitions they undergo. Some computational studies attribute functional interpretation to different dynamical states of models. In this regard, special credit should be given to earlier work on spiking attractor networks (Amit and Brunel 1997; Compte et al. 2003; Lundqvist et al. 2010a, b) used to simulate a so-called

memory delay period when humans and primates held one or several items in working memory. The network dynamics during memory-coding interval is qualitatively different from that exhibited beforehand. More recently, the abundant work on cortical attractor models by Lundqvist and Herman (Lundqvist et al. 2011, 2013a, b, c; Herman et al. 2013) deserves here special attention since their biophysically detailed networks have been used to simulate a wide range of memory processes and perceptual phenomena with strong oscillatory correlates in agreement with biological data. In Lundqvist et al. (2011) and Herman et al. (2013), endogenous periodic switching between different network states with distinct spectral manifestations and functional meaning was reported. In particular, transitions from a memory-coding state accompanied by elevated spectral power in theta and gamma bands to a noncoding idling regime with increased alpha-band activity and suppressed theta-gamma correlates, and vice versa, serve as a prime example of intrinsically driven modulation of the model's oscillatory dynamics. It should be added here that such switching dynamics mediated by neural adaptation as well as short-term synaptic plasticity (depression and augmentation) can be linked to a so-called periodic memory replay phenomenon implicated in working memory maintenance (Sandberg et al. 2003; Fuentemilla et al. 2010; Lundqvist et al. 2011; Herman et al. 2013). Another modulatory effect in attractor network models simulating working memory is associated with varying oscillatory power in theta, alpha, and gamma frequency bands depending on the memory load, i.e., the number of memory items to be replayed by the network (Herman et al. 2013). This phenomenon has been widely reported in experimental studies (e.g., Raghavachari et al. 2001; Jacobs and Kahana 2009). All these effects can be explained by the so-called bistability of the network dynamics (it can exhibit two qualitatively different regimes of operation), controlled by the interaction of excitatory and inhibitory cells, and by synaptic (Wang et al. 2006; Mongillo et al. 2008) and neural mechanisms regulating lifetime of memory-coding states.

Changes or transitions of the dynamical regime of neural network models can also be induced by external stimuli. As a result, a stimulus drives the modulation of the model's ongoing oscillatory dynamics. This was the original approach to simulating a memory delay period (Amit and Brunel 1997; Compte et al. 2003; Lundqvist et al. 2006), where the stimulus forced cells in the targeted cell assembly to fire at an elevated rate, simultaneously suppressing the activity in other cells not belonging to the given assembly. This suppression is usually mediated by disynaptic inhibition via a population of interneurons. As mentioned earlier, in a biologically detailed version of such attractor networks (Lundqvist et al. 2006, 2010a, b, 2013a, b, c; Herman et al. 2013) interactions between pyramidal and basket cells in layers 2/3 mediate the competition between different memory patterns and produce at the same time gamma-like oscillations following a stimulus presentation. There have also been other detailed models devised to study the impact of stimulation on oscillatory power changes (Jones et al. 2009). However, they did not have a clear functional interpretation.

Imposed Rhythmic Modulation of Neural Dynamics in Computational Models

A study on functional and dynamical implications of infra-slow fluctuations in a cortical model (Lundqvist et al. 2013a) serves as one of the most representative examples of imposing rhythmic modulation in a network by an external source. The authors used an attractor network to simulate a threshold-stimulus detection task and imposed a slow sinusoidal modulation (~ 0.1 Hz) of excitatory noise onto each principal cell with the aim of generating a slowly varying oscillatory component in the synthesized field potentials. This allowed for investigating its effect on processing weak stimuli. Since the original network without a sinusoidal noise source produces oscillatory activity in three distinct frequency bands roughly corresponding to electrophysiological theta, alpha, and gamma depending on the current

functional and dynamical state, as a result of introducing the aforementioned fluctuating component, a strong phase-amplitude coupling emerged. In other words, a modulatory effect of the phase of the slow fluctuations on the power of faster rhythms (>1 Hz) was obtained in agreement with experimental data (Monto et al. 2008) and in line with the concept of nested oscillations (cf. section “Models of Nested Oscillations”).

Another prominent example of inducing oscillatory behavior in a model and studying the emergent modulatory dynamics is a combined simulation and experimental study by Jones et al. (2009). In their laminar model of somatosensory cortex, both feedforward and feedback pathways were stimulated with exogenous 10 Hz spiking input mimicking Rolandic mu rhythm. For the feedforward pathway layer 4 served as the target, whereas for the feedback pathway, the input was delivered to distal dendrites of layer 2/3 cells. By manipulating the relative timing of these inputs, the authors could study properties of the total modulated rhythmic activity and its effect on evoked sensory responses in a simulated somatosensory task.

Models of Nested Oscillations

Nested oscillation is a phenomenon where the phase of underlying slow rhythm modulates the power of faster oscillations. It has been a prominent finding for theta and gamma rhythms, particularly in memory tasks (e.g., Chrobak and Buzsaki 1998; Canolty et al. 2006; Jensen and Colgin 2007; Kendrick et al. 2011). This classical example of cross-frequency modulatory dynamics has received some attention in the computational neuroscience community. It has been modeled in both hippocampal networks (White et al., 2000; Rotstein et al. 2005; Neymotin et al. 2011) and cortical models (Kendrick et al. 2011; Herman et al. 2013). The origin of oscillatory nesting is still a matter of debate. In modeling work the emphasis has so far been on the role of intrinsic properties of interneurons (White et al. 2000; Tiesinga et al. 2001; Rotstein et al. 2005;

Neymotin et al. 2011). For generating a slower theta rhythm, Neymotin et al. (2011), Rotstein et al. (2005), and White et al. (2000) relied on a specific subtype of interneurons with slow synaptic dynamics (oriens lacunosum moleculare) due to their prevalence in hippocampus. In Rotstein et al.'s (2005), their coupling with fast-spiking interneurons was needed to sustain synchronized rhythmic activity at a population level. Then, as a result of special tuning of the coupling parameters to avoid interneurons firing without phasic excitation and with introduction of AMPA-mediated excitation, the authors managed to obtain the effect of nested oscillations. A similar circuit of interneurons with fast and slow synaptic dynamics was proposed by White et al. (2000) as main contributors to hippocampal rhythms. Neymotin et al. (2011), on the other hand, introduced an additional external driving input to oriens lacunosum moleculare interneurons from medial septum. Then, to generate gamma-band activity, classical basket-pyramidal cell loop was exploited, also enhanced by medial septum. Modulatory effect of theta rhythm with respect to the amplitude of gamma oscillations was obtained due to the coupling between two different types of interneurons in certain analogy to Rotstein et al.'s (2005) and White et al.'s (2000) minimalistic models. Similarly, the neural network model developed by Kendrick et al. (2011) exhibited theta-nested gamma as a result of combining fast and slow inhibitory interneurons. Interestingly, the model allowed the authors to investigate functional consequences of changing the ratio between theta and gamma, as a potential effect of learning. Their simulation results suggested that shallow nesting of gamma on theta, reported experimentally in inferotemporal cortex in a learning scenario, optimized coupling between the two rhythms and maximized responses in the downstream neurons.

A different approach to phase-amplitude modulation was adopted in a cortical laminar model proposed by Kramer et al. (2008). The authors suggested that layer interactions lead to the emergence of lower-beta rhythm as a result

of period concatenation of simultaneous faster rhythms. In another cortical model the occurrence of theta-gamma coupling in layer 2/3 was obtained as a result of the attractor dynamics mediated by recurrent connectivity (Herman et al. 2013). While the neural mechanism underlying gamma-band activity was analogous to the other models, i.e., local inhibitory-excitatory loop, the slower rhythm reflected the activation of a distributed memory pattern in the network stored by means of the aforementioned long-range recurrent connections. Most importantly, due to this functional aspect of the dynamics of theta-gamma modulation, Herman et al.'s (2013) model lends itself to an interpretation of a computational role of nested oscillations. In the context of memory and learning, one could hypothesize that slow and spatially coherent rhythm would provide a window for bursting and synaptic wiring of cell assemblies whereas the local populations constituting an assembly would exhibit activity on faster timescales corresponding to gamma rhythm. In that framework, gamma oscillations would mediate local computations, possibly of competitive nature.

Attentional and Neuromodulatory Effects on Oscillatory Dynamics in Computational Models

Neuromodulation provides another dimension to the dynamics of neural networks by modifying intrinsic properties of neurons and synapses (Marder and Thirumalai 2002; Marder 2012). Although there have been a number of computational studies that attempt to enhance our understanding of the computational role of neuromodulation (Fellous and Linster 1998), less attention in modeling work has been given to its implications for the oscillatory dynamics in neural circuits. Historically, it is important to mention theoretical studies on extrinsic neuromodulation of thalamic reticular cells (Destexhe et al. 1994) and the effects of cholinergic modulation on the olfactory cortex (Liljenström and Hasselmo 1995). Destexhe

et al. (1994) illustrated that a neuromodulator starts a cascade of cellular processes that leads to burst activity of single neurons, which generates population oscillations in the frequency range of spindle waves. Liljenström and Hasselmo (1995) contributed to the understanding of the implications of acetylcholine effects at the cellular level for cortical oscillations. In a rather simple model of EEG and field potentials recordings from the piriform cortex, they managed to explain the mechanism of altered evoked gamma oscillations and demonstrated how suppression of both neural adaptation and intrinsic excitatory synaptic transmission coupled with the activation of inhibitory interneurons mediated dynamical shifts between non-oscillatory and theta rhythmic regimes. More recently, the mechanism underlying cholinergic neuromodulation in the olfactory system was scrutinized in a biophysical model of the olfactory bulb (Li and Cleland 2013). Muscarinic neuromodulation was shown to strengthen the gamma-band oscillatory component in the synthesized bulbar local field potential.

A neuromodulation phenomenon has also been linked to attentional modulation of the neural dynamics. In a few computational studies, the effect of attention on basic stimulus processing has been demonstrated using a biased competition approach. The basic idea is that a slight additional external input to one of the competing neural populations (attended) is amplified and the activity in the other population (non-attended) is suppressed (Deco and Thiele 2009). A desirable feature of these attention models is the emergence of synchronization of neural activity in the gamma band consistently with experimental data (Fries et al. 2001). Such attention-induced effects of synchrony enhancement can be obtained by decreasing neural adaptation, which could reflect cholinergic modulation (Börgers et al. 2005). Alternatively, cholinergic-mediated reduction of inhibitory drive on excitatory cells can be used as a biasing mechanism (Buia and Tiesinga 2006; Börgers et al. 2008). Gu and Liljenström (2007) simulated different effects of cholinergic modulation on extracortical and

intracortical projections in a multilayer cortex and obtained the effect of attentional increase of gamma-band synchronization in the superficial layers.

Computational Models of Motor Pools

C. J. Heckman

Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Definition

The *motor unit* comprises the motoneuron, its axon, and all the muscle fibers innervated by the axon's terminal branches (Heckman and Enoka 2012). The muscle fibers for one motor unit are sometimes referred to as the *muscle unit*. Each muscle is innervated by a pool of motoneurons in the ventral portion of the spinal cord or, for the face and neck, in the brainstem. Thus, the *motor unit pool* comprises all the motoneurons in one motor nucleus and the muscle innervated by those motoneurons. In contrast, a *motor pool* only includes the motoneurons.

Detailed Description

The motor unit pool has long been an appealing target for computational modeling of a neural network. Efforts at modeling this fundamentally important system date back more than 50 years, to Wilfred Rall's early interest in the input–output relations of the monosynaptic reflex arc (Rall 1955). But the system is inherently a neuromechanical one and the first models of motor unit pools in the 1960s and 1970s, Henneman and Burke, were based solely on recruitment of motor units at their maximum

forces to clearly illustrate the neuromechanical nature of the system (Kernell 2006). The key point is the great diversity of motor unit properties and their organization via Henneman's size principle (Henneman and Mendell 1981). Burke defined motor unit types to express this diversity (S (slow), FR (fast, fatigue resistant), and FF (fast, fatigable)) (Burke 1981), but all electrical and mechanical properties exhibit a continuous variation (Heckman and Enoka 2012). S motor units have motoneurons with low thresholds to synaptic activation, innervate relatively few muscle fibers, and thus produce small force. These fibers are all slow but have tremendous fatigue resistance. FRs and FFs have progressively higher thresholds for their motoneurons, greater forces and speeds, but lower fatigue resistances for their muscle units. These differences are not small: threshold varies tenfold, force more than tenfold, speed fivefold, and fatigue more than tenfold (Kernell 2006). The recruitment models by Henneman established that this sequence is optimal for fatigue resistance, energy efficiency, and precision of motor output. Burke and colleagues used this recruitment model approach to show how usage of motor units compared to the forces and speeds required in a wide range of movements. Posture can be accomplished by recruitment solely of S units, while FF units only become important for high speeds and forces.

More detailed models of motor unit pools by Heckman and Binder (1991) and by Fuglevand et al. (1993) in the early 1990s included rate modulation and revealed that the overall form of the motor pool input–output function was sigmoidal, with progressive recruitment of larger motor units at low levels giving way to saturation of forces at high levels. The Heckman and Binder work was designed to understand how the organization of synaptic input to the system affected motor output; this approach continues and has led to improved understanding of how neuromodulatory inputs that alter the electrical properties of motoneurons are fundamental in shaping normal motor output (Heckman and Enoka 2012). The work by Fuglevand and colleagues has inspired many studies of the structure

of the output in human subjects, such as relations between force and EMG (Heckman and Enoka 2012). Models have now progressed to where the distortions in motor units that occur in injury and neurodegenerative diseases are beginning to be explored (e.g., Elbasiouny et al. 2010; Venugopal et al. 2011). In all these efforts, a major advantage of this system is the close correspondence between theory and experiment that it affords. Many of the key parameters of motoneurons can be measured by intracellular recordings in animal preparations, while all of the output variables, including not only muscle force and EMG but also firing patterns of single motor units, can be measured in humans. Thus, motor pool computational models continue to provide unique insights into the structure of motor commands in both normal and pathological states.

Definition

Computational models of the neural retina are extremely useful in the understanding of normal and abnormal retinal responses to light. They can also be for investigating retinal responses to artificial stimuli such as electrical stimulation by a vision prosthesis. Depending on the aims, complexities, and physiological assumptions on which the model is based, computational models of the retina may be classified into six broad types: single-compartment, morphologically realistic, block-compartment, discrete-neuronal network, continuum, and empirical models of retinal function.

Introduction

The retina is an elaborate architecture of neurons interconnected through gap junctions and synapses. At the outer retina, an array of rod and cone photoreceptors converts the incident light to neural responses. These signals then pass through approximately ten types of cone and one type of rod bipolar cell before arriving at the output neurons in the inner retina – the retinal ganglion cells (RGCs). RGC axons that form the optic nerve then transmit the signals in the form of action potentials to the brain (Masland 2012; Roska and Meister 2014). In addition to this vertical excitatory pathway, the retina also contains two lateral inhibitory pathways. In the outer retina, the

horizontal cells provide inhibitory feedback onto the photoreceptors and inhibitory feedforward onto the bipolar cells. In a similar scheme, the amacrine cells in the inner retina provide inhibition of the bipolar cells and the RGCs (Masland 2001).

Existing anatomical and neurophysiological knowledge of retinal function has permitted computational models to reproduce aspects of retinal responses to either visual or artificial electric stimuli at various levels of complexity. In turn, these models have helped sharpen our understanding of retinal function, particularly in how intrinsic biophysical and morphological properties at the cellular level, and integration of synaptic inputs at the network scale, contribute to retinal function. Over several decades, computational models provided important insights in understanding the response dynamics and computations of single retinal neurons, along with their functional contributions in the larger neural network.

Despite these major advances, significant aspects of retinal function remain to be described. For instance, experimental studies increasingly indicate that the function of many retinal neuron types is more intricate than originally thought (Zhang et al. 2012; Hosoya et al. 2005; Freed 2001; Fried et al. 2002; Masland 2012; Gollisch and Meister 2010; Baden et al. 2016). Similarly, at the frontiers of retinal electrostimulation, the mechanisms underlying the large diversity in retinal neuronal responses to artificial electrical stimulation are still being investigated (Twyford et al. 2014; Freeman et al. 2011; Felsen and Dan 2005; Guo et al. 2018; Yang et al. 2018).

On a microscale, retinal neurons extract their preferred visual information; process this information, often with the help of other neurons; and then transfer the results to downstream neurons. A single neuron can be represented by either a single-compartment model, a morphologically realistic model, or via a block-compartment approach, depending on the aims, complexities, and physiological assumptions on which the model is based. Such models integrate electrophysiological current/voltage clamp recordings and biophysical principles into a mechanistic understanding of individual neuronal properties,

reconstructing ionic mechanisms hidden in the data, as well as utilizing new experimental information to improve existing model structures.

On a larger scale, visual information is arrayed across large inhomogeneous populations of neurons within each retinal layer. One approach of representing such neuronal networks involves bringing together individual neurons, each being a complete model capable of stand-alone execution, and connecting them together with the computational representation of synapses. As such, these models are generally mechanistically detailed, but computationally expensive to run. Alternatively, empirical models could also be used to construct large-scale models of the retinal function. Unlike the aforementioned approach, these models aim to capture only the input-output relationship of the neuron/network by treating the constituent neurons as black boxes (Pillow et al. 2005; Pillow et al. 2008). By omitting neuronal morphological details, and often the associated ionic biophysics too, these approaches have the advantage of computational efficiency. These large-scale tissue- or network-based models have been used to investigate how each retinal neuron contributes to a particular subcircuit or entire retinal tissue and how they work together to collectively encode visual input. Irrespective of the modeling techniques, they offer a better understanding of the growing amount of experimentally recorded retinal responses to light or electrical stimuli and can be used to make testable predictions. For clinical applications, some of these models also provide valuable insights into the development of effective stimulation strategies for visual prostheses (Luo and Da Cruz 2014; Halupka et al. 2017; Barriga-Rivera et al. 2017; Loizos et al. 2018; Tsai et al. 2017; Yang et al. 2018). This chapter examines the current state of the art of computational models of the neural retina, across different scales, and discusses their advantages, limitations, and future potential.

Single-Compartment Models

Single-compartment models (see Fig. 1, level I) have been used to simulate nearly all retinal

Computational Models of Neural Retina, Fig. 1 Six types of computational models typically used in retinal neuron modeling. I. Single-compartment models, II. morphologically realistic models, III. block-compartment models, IV. discrete-neuronal network models (adapted from (Publio et al. 2009)), V. continuum models, and VI. empirical models of retinal function (adapted from (Halupka et al. 2017)). Depending on the study aim, a single-compartment neuron model can be extended to any biophysical model type (II, III, IV, V), by

adding new assumptions such as anatomical structure, synaptic, or interneuron coupling information. Conductance-based models (i.e., types I, II, and III) can be used as individual neuron elements in both continuum models and discrete-network models. Empirical models are often used in building retinal networks or the whole visual system. Large-scale network models can capture the essential function of photoreceptors, bipolar cells, and RGCs, as well as the contribution of retinal heterogeneity in visual information processing

neuron types, including photoreceptors (Kamiyama et al. 1996; Publio et al. 2006; Kourennyi et al. 2004), horizontal cells (Aoyama et al. 2005; Usui et al. 1996b; Shirahata 2008), bipolar cells (Usui et al. 1996a), amacrine cells (Steffen et al. 2003; Shirahata 2011), and a range of RGC types (Fohlmeister and Miller 1997a; Fohlmeister et al. 1990; Guo et al. 2012; Kameneva et al. 2011; Qin et al. 2017). These

models approximate the structure of the neural excitable membrane using a capacitance to mimic the membrane phospholipid bilayer, in parallel with several conductors to mimic transmembrane channels composed of proteins. The relationship between the transmembrane potential and membrane currents is described by the following ordinary differential equation (ODE):

$$J_m = C_m \frac{dV_m}{dt} + J_{\text{ion}} + J_{\text{stim}} = 0 \quad (1)$$

where J_m denotes total membrane current density (current per unit membrane area), V_m represents membrane potential, C_m represents membrane capacitance per unit area, and J_{ion} represents the total ionic current density (Aidley 1979). A single-compartment model assumes no net current across the cell membrane ($J_m = 0$), since all current flowing through the ionic channels charges the membrane capacitance. This is also known as the space-clamped condition. Furthermore, the neuron may be activated by an intracellular stimulus current density (J_{stim}) delivered into the cell, to mimic experimental manipulation during intracellular recordings.

Since ionic mechanisms of retinal neurons are far more complex than those of the classic Hodgkin-Huxley ionic model of the squid giant axon (Hodgkin and Huxley 1952), many modelers have chosen to modify the classic model, extending it to replicate the known ionic mechanisms in various retinal neurons. Among the first ionic models developed for the retina were those for the RGCs. Their all-or-none spiking behaviors are close to the classical notion of neurons and are thus easily modeled by modifying existing Hodgkin-Huxley-type formulations. A landmark in RGC modeling was the Fohlmeister-Coleman-Miller (FCM) formulation (Fohlmeister et al. 1990; Fohlmeister and Miller 1997a, b). This model was based on voltage clamp studies in the tiger salamander retina. It contained five intrinsic ion currents underlying RGC spiking. Prior to these studies, experimental knowledge of detailed ion channel kinetics or their neuronal distribution was rarely used in retinal neural modeling. The FCM model also included intracellular calcium dynamics responsible for temporal spiking properties. With more optimized Na^+ and K^+ gating kinetics, the FCM model demonstrates many advantages over the original Hodgkin-Huxley formulation in terms of impulse encoding flexibility (Fohlmeister 2009), revealing its ability in reconstructing a large range of neuronal spiking behaviors. Since its publication, this model and its derivatives have led to further quantitative understanding of many dynamical phenomena in RGCs, including spike-frequency

adaptation (Fohlmeister and Miller 1997a), rebound activation (Guo et al. 2012; Kameneva et al. 2011), burst firing (Kameneva et al. 2011), and subthreshold activities (Kameneva et al. 2011).

Moreover, the single-compartment FCM model was also validated in higher-dimensional simulations with detailed anatomical information or network interactions. To the best of our knowledge, Fig. 2 illustrates nearly all applications and extensions based on FCM formulations in the last two decades. Its morphological-, tissue-, and network-based extensions are discussed in the following sections.

Despite the reported functional significance of all five ionic currents in the FCM model, relatively simpler ionic models were still used to study specific RGC response properties when accurate impulse generation was not required (Carras et al. 1992; Al Abed et al. 2013; Boinagrov et al. 2010), as well as for other retinal neurons (e.g., photoreceptors or bipolar cells) (Taylor et al. 1995; Aoyama et al. 2005).

The advantage of simplicity in a single-compartment model is also its weakness. Certain disparities between the single-compartment FCM model and known biological RGC behavior cannot be reconciled by optimizing the model parameters alone (Fohlmeister and Miller 1997a). Having additional neuronal compartments that differ in both size and ionic channel density could also produce more realistic spike generation and propagation (Carras et al. 1992). Recent brain cell studies suggest that models cannot capture subtle response characteristics, such as fast depolarization during action potentials, without incorporating representations of axons and dendrites and the propagation of current along these neurites (McCormick et al. 2007; Mainen and Sejnowski 1996; Herz et al. 2006). Therefore, rather than simply incorporating intrinsic properties at a single point, spatial anatomical information and ionic channel distribution are also required for accurate neuronal modeling.

Morphologically Realistic Models

Toward the goal of creating models that represent their biological counterpart more closely,

morphologically realistic models (see Fig. 1, type II) are based on detailed anatomical representations of the physical structural components in biological neurons, including soma, axon initial segment (AIS), axon hillock (AH), the distal axon, and dendrites. Such models are ideal for studying how cell morphologies and nonuniform distributions of ionic channels contribute to neuronal response dynamics and how these affect function. Morphologically realistic models provide a good approximation of biological neuronal behavior and have been largely used to build structurally “complex” retinal neurons such as amacrine cells and RGCs. These models can sometimes include more than 1000 morphological segments to ensure accurate spatial resolution (Fohlmeister et al. 2010).

In morphological cable models, membrane potential is both space and time-dependent, necessitating the modification of Eq. (1) as follows:

$$\begin{aligned} J_m &= \frac{\partial}{\partial s} \left(\frac{r\sigma_i}{2} \frac{\partial V_m}{\partial s} \right) \\ &= C_m \frac{\partial V_m}{\partial t} + J_{\text{ion}} + J_{\text{stim}} \end{aligned} \quad (2)$$

where s is the arc-length distance along the neuron, r is the local radius of the neuron which can vary with s , and σ_i is the intracellular conductivity.

In practice, Eq. (2) is approximated by separating the neuron into multiple discrete regions, each region associated with its own ionic properties and connected with neighboring compartments by axial conductors. The more compartments are used, the closer the model tends toward the biological neuron.

An advantage of this type of model is that it can also simulate cell responses to extracellular electrical stimulation, as opposed to only intracellular stimulation in the single-compartment model (a single-compartment model assumes no net current across the cell membrane). In this situation, membrane potential is calculated by taking the difference between intracellular potential V_i and extracellular potential V_e :

$$V_m = V_i - V_e \quad (3)$$

where V_i is derived from

$$\frac{\partial}{\partial s} \left(\frac{r\sigma_i}{2} \frac{\partial V_i}{\partial s} \right) = C_m \frac{\partial V_m}{\partial t} + J_{\text{ion}} \quad (4)$$

and the extracellular voltage distribution can be simulated by either a monopolar point source (Greenberg et al. 1999; Jeng et al. 2011) or a disk electrode (Greenberg et al. 1999; Tsai et al. 2012; Jeng et al. 2011), modeled as

$$V_e = \rho_e I / 4\pi r \quad (5)$$

$$\text{or } V_e = \frac{2IR_s}{\pi} \arcsin \left(\frac{2R}{\sqrt{(a-R)^2 + z^2} + \sqrt{(a+R)^2 + z^2}} \right) \quad (6)$$

where ρ_e denotes the resistivity of the retinal extracellular solution; I is the extracellular stimulus current; r is the distance between the stimulating electrode and the point at which the voltage is being computed; a and z are the radial and axial distance, respectively, from the center of the disk for $z \neq 0$; R is the radius of the disk; and R_s is the electrode transfer resistance. Note that Eqs. (5) and (6) are applicable to infinite and semi-infinite homogeneous media, respectively.

In some cases, the extracellular voltage distribution has been coupled to the local membrane potential (Abramian et al. 2011) and given by

$$\frac{\partial}{\partial s} \left(-\frac{r\sigma_e}{2} \frac{\partial V_e}{\partial s} \right) = C_m \frac{\partial V_m}{\partial t} + J_{\text{ion}} \quad (7)$$

where σ_e denotes the extracellular conductivity.

Neuronal morphology can influence the flow of intracellular currents between neighboring compartments through the cell membrane and by intracellular conductance. As a result, morphology may also contribute to the unique spiking behavior of different RGC types (Sheasby and Fohlmeister 1999). Although dendritic morphologies and stratifications of RGCs have been examined extensively, their contribution to RGC spiking patterns is not well understood, owing to the difficulty of isolating and manipulating such

properties in the experimental preparation. However, the morphologically realistic modeling approach can quantitatively control a variety of cellular properties, including morphology, and isolate their contributions in shaping firing patterns (Guo et al. 2013b, c).

Notable examples of morphologically realistic retinal neuron models include (a) the FCM (1997) model (Fohlmeister and Miller 1997b), which is the first morphologically detailed RGC formulation, able to closely reconstruct action potential shapes and spiking properties; (b) the Sheasby-Fohlmeister (1999) realistic RGC encoder (Sheasby and Fohlmeister 1999), used to explore the effect of regional ionic channel distributions along the cellular morphology; (c) the Schachter et al. (2010) model (Schachter et al. 2010), able to explain the mechanisms of active dendritic processing of synaptic inputs in direction-sensitive RGCs; and (d) the Jeng et al. (2011) sodium channel band model (Jeng et al. 2011) that enabled the determination of the factors underlying action potential initiation site in response to electrical stimulation of RGCs.

These morphologically detailed modeling approaches offer important information on how their channel distributions influence RGC firing patterns and how the interaction between different cell regions influences the neural coding. The recent morphologically realistic model of Abbas et al. (Abbas et al. 2013) suggested that dendritic ionic channels provide RGCs with the ability to code “looming” motion. Another recent study by Maturana et al. (Maturana et al. 2013) focused on how physical properties of RGCs contribute to their specific spiking response patterns in response to electrical stimulation.

Experimental findings have also suggested that RGC dendrites exhibit regenerative spikes, as opposed to being simply passive neurites (Velte and Masland 1999; Oesch et al. 2005; Sivyver and Williams 2013). The detailed dendritic structure of morphologically realistic models can provide the framework for investigating dendritic signal processing, since the physical properties can be precisely controlled in these models. Furthermore, the dendritic active conductances can be modulated *in silico*, to study their effects on RGC

spiking properties (Guo et al. 2013c). In summary, the realistic neuron modeling approach provides a promising tool for studying soma-dendritic interactions, assisting in interpreting experimental studies in dendritic patch-clamp recordings, fluorescent imaging, and immunocytochemical channel localization techniques.

Other than their application to RGCs, morphologically realistic models have also been applied to amacrine cells. These cells also demonstrate a large diversity in functional properties (Vigh et al. 2000; Yang et al. 1991). A morphologically realistic starburst amacrine cell model was developed by Fohlmeister et al. to study mechanisms underlying local dendritic processing (Fohlmeister et al. 1990). By testing different artificial morphologies, another amacrine modeling study by Tukker et al. (Tukker et al. 2004) suggested that directional sensitivity may mainly depend on a sufficient number of synaptic inputs at the distal dendrites rather than the dendritic morphology itself. Another amacrine modeling study by Miller et al. (2006) suggested that various amacrine cell spiking properties could be reproduced by a RGC model with minimal parameter adjustment (Miller et al. 2006), revealing the close ionic relationships between some amacrine cells and RGCs.

Although certain morphologically realistic retinal neuron models have also been used in constructing accurate models of local circuits or the whole-tissue retina, to study neuronal interactions during electrical stimulation (Greenberg et al. 1999; Resatz and Rattay 2004; Rattay et al. 2003; Rattay and Resatz 2004; Loizos et al. 2014, 2016, 2018), their huge computational demand has resulted in their restricted use for population-based simulations, especially in large-scale network modeling.

Block-Compartment Models

An alternative modeling strategy, block-compartment modeling (see Fig. 1, type III), represents only a few neuronal regions. This is a compromise between computational efficiency and biological realism. These models can be considered as a simplified version of the morphologically realistic approach,

extracting the most essential anatomical information to provide high computational efficiency with minimal neural structure.

The simplest model in this genre is a two-compartment system coupled by a linear conductor, representing a soma and a dendritic or axonal compartment. In this way, Eq. (2) can be updated as follows:

$$\begin{aligned} \frac{G_c}{p}(V_x - V_s) &= C_m \frac{dV_s}{dt} + J_{\text{ion},s} \\ \frac{G_c}{1-p}(V_s - V_x) &= C_m \frac{dV_x}{dt} + J_{\text{ion},x} \end{aligned} \quad (8)$$

where V_s and V_x represent the membrane potential in the soma and connected compartment, respectively, G_c is the coupling conductance between compartments, p is the percentage of the cell membrane area taken up by the soma, and $J_{\text{ion},s}$ and $J_{\text{ion},x}$ are the membrane potentials of the soma and connected compartment, respectively.

This morphology-reducing process depends largely on the motivation of specific studies, as well as the ionic mechanisms involved. Previous findings have suggested that reasonably realistic RGC spiking patterns, comparable to experimental recordings and simulations from morphologically realistic models, can be obtained using only four neuronal compartments (dendrites, soma, thin segment, and axon) (Fohlmeister and Miller 1997b). A single unbranched dendritic compartment, which allowed regionally specific activation of individual channel subtypes, was shown to be sufficient to elicit summation of excitatory postsynaptic potentials (EPSPs) in RGCs (Abbas et al. 2013). In addition, a simplified axonal activation model was able to successfully predict RGC experimental threshold profiles, as well as the initial activation location in response to electrical stimulation (Abramian et al. 2011). In another model investigating the origin of AP initiation in RGCs, the dendrites were reduced to unbranched cables of uniform diameter (Carras et al. 1992). Moreover, another such simplified RGC-structure model was used to investigate how epiretinal electrical stimulation could result in the production of punctate phosphenes, as

opposed to diffuse or streaked perceptions that would be consistent with the recruitment of axons from distant RGCs (Schiefer and Grill 2006). In a more recent tissue-based retinal model, each point in the RGC layer was represented by an active soma and a passive dendritic compartment, with a synaptic input into dendrites included to approximate the underlying neural structure (Al Abed et al. 2013).

Apart from RGC models, equivalent cable representations have also been used to simulate starburst amacrine cells (Poznanski 1992; Enciso et al. 2010; Tukker et al. 2004). These models incorporated various levels of simplified cylindrical dendritic structures and were helpful in elucidating the influence of morphological structure on the mechanisms underlying directional sensitivity in starburst amacrine cell networks.

Block-compartment models have also been applied to morphologically simple neurons such as photoreceptors (Taylor et al. 1995), bipolar cells (Mennerick et al. 1997), and horizontal cells (Usui et al. 1996b; Smith 1995) (see Table 1). Most of these retinal neuron types do not demonstrate a significant morphological diversity and only require a simple physical structure such as a cylindrical soma connected to an axon terminal.

One question that must be answered in block-compartment models is to what extent can retinal neurons be simplified without compromising realistic cell behavior? A general principle is that models should be at the simplest level required to reproduce desired behavior of a physical system. This also raises another question: to what extent does neural morphology contribute to its response? A recent study by Guo et al. (2013b) provided an example showing the contribution of morphology to cell responses. They showed that RGC models could reproduce distinct variations in spiking patterns in response to intracellular current injection by solely varying their morphology, with all biophysical parameters describing voltage-gated channel kinetics and distributions remaining unchanged. In addition, the spatial distribution of membrane ion channel densities among the various neural compartments also contributes to the neuronal response.

Computational Models of Neural Retina,

Table 1 Different types of retinal neurons can be characterized into multiple model types. RR, CR, HC, and BC models are largely limited to single-compartment and block-compartment models due to their relatively simple morphology. Morphologically complex neurons such as

ACs and particularly RGCs are represented at all types. Empirical models can reproduce the functional input-output relationship between light stimulus inputs and cell responses in nearly every retinal neuron type without considering the detailed biophysical structure of the neuron

Neuron type	Model type			
	Single-compartment model	Morphologically realistic model	Block-compartment model	Empirical model
Rod photoreceptor (RR)	Kamiyama et al. (1996), Kourennyi et al. (2004), Ogura et al. (2003), Publio et al. (2006)		Taylor et al. (1995)	Hood et al. (1993), Hamer et al. (2005), Lamb and Pugh (1992)
Cone photoreceptor (CR)	Baylor et al. (1974), Kourennyi et al. (2004), Vallergera et al. (1980), Publio et al. (2009)		Smith (1995), Taylor et al. (1995), Tsai et al. (2017)	van Hateren and Snippe (2007), Teeters et al. (1997), Shah and Levine (1996a), Shah and Levine (1996b)
Horizontal cell (HC)	Usui et al. (1983), Aoyama et al. (2005), Shirahata (2008)		Usui et al. (1996b), Smith (1995), Tsai et al. (2017)	
Bipolar cell (BC)	Publio et al. (2009), Usui et al. (1996a)		Mennerick et al. (1997), Werginz et al. (2015)	Robson and Frishman (1996), Robson and Frishman (1995)
Amacrine cell (AC)	Publio et al. (2009), Shirahata (2011), Steffen et al. (2003), Smith and Vardi (1995)	Velte and Miller (1997), Miller et al. (2006)	Enciso et al. (2010), Poznanski (1992), Tukker et al. (2004)	Saglam et al. (2009)
Retinal ganglion cell (RGC)	Fohlmeister et al. (1990), Fohlmeister and Miller (1997a), Guo et al. (2012), Kameneva et al. (2011), Publio et al. (2009), Boinagrov et al. (2012), Qin et al. (2017)	Fohlmeister et al. (2010), Fohlmeister and Miller (1997b), Guo et al. (2013a), Jeng et al. (2011), Sheasby and Fohlmeister (1999), Tsai et al. (2012), Greenberg et al. (1999), Maturana et al. (2013), Schachter et al. (2010), Schiefer and Grill (2006), Velte and Miller (1995), Carras et al. (1992), Rattay and Resatz (2004), Rattay et al. (2003), Resatz and Rattay (2004), Abbas et al. (2013), Publio et al. (2012), Yang et al. (2018), Guo et al. (2019)	Abramian et al. (2011), Carras et al. (1992), Al Abed et al. (2013), Abbas et al. (2013), Fohlmeister and Miller (1997b), Werginz et al. (2014)	Cai et al. (2007), Keat et al. (2001), Victor (1987), Victor (1988), Hosoya et al. (2005), Pillow et al. (2005)

Since there is no generally clear simplification approach in block-compartment neural modeling, an alternative approach comprises iterative morphometric simplification, wherein the reducing process is stopped when the model fails to reproduce biological cell responses. Although the influence of systematic morphologic perturbations in neuronal behavior has been reported in several brain cell studies (van Elburg and van Ooyen 2010; Mainen and Sejnowski 1996), no similar approach has been used yet in retinal neuron modeling. A morphometric simulator was developed recently to study how dendritic intersections, branching points, and terminal tips contribute to correct classification of RGC images (Ristanovic et al. 2009). One could imagine, for example, the integration of such a morphometric generator into a modeling framework, to create a platform for exploring the ramifications of RGC morphological variations (Wong et al. 2012; O'Brien et al. 2002; Rockhill et al. 2002).

Discrete-Neuronal Network Models

The retinal network can also be simulated by grouping discrete retinal neuron elements, based on techniques described earlier, with excitatory and inhibitory synaptic interactions. In addition to neural properties and stimulus parameters, these discrete-neuronal network models (see Fig. 1, type IV) also take into consideration the influence of forward and feedback connections among neurons, as well as the physical architecture of the retina.

A discrete-neuronal network model can represent either the entire retinal structure (Wohrer and Kornprobst 2009) or a retinal subsystem, including the cone-rod network (Smith et al. 1986), the rod bipolar network (Robson and Frishman 1996), the cone-horizontal cell circuit (Smith 1995), the horizontal cell layer (Usui et al. 1996b), the rod pathway (Publio et al. 2009), the cone pathway (Arguello et al. 2013; Cottaris et al. 2005; Teeters et al. 1997), the amacrine network (Smith and Vardi 1995), bipolar-RGC interactions (Rattay et al. 2003), and RGC layer (Publio et al. 2012).

Most discrete-neuronal network models do not focus on physiological precision in individual neurons but on the functional output of the retina on a large scale. They are generally constructed using non-biophysical neuron formulations such as cascaded models. This allows them to include a large number of cells with multiple visual pathways rather than specific local microcircuits while remaining computationally tractable. As such, these models can be very effective for investigating complex neural networks containing a large number of cells of different types. For example, one large-scale retinal model, comprising up to 10^5 neuron elements, was able to achieve both accurate physiological behavior and reasonable computational efficiency (Wohrer and Kornprobst 2009). Another study examined the contribution of different cell subclasses in a large RGC population, facilitating the development of testable population-based hypotheses (Bomash et al. 2013). In addition, these functional network models have also been used to provide a comprehensive description of electroretinogram (ERG) generation using only local rod bipolar circuits (Robson and Frishman 1996). They can also qualitatively explain various types of adaptation during visual information processing (Hosoya et al. 2005).

Some discrete-neuronal network models also incorporate detailed descriptions of retinal connectivity in successive neural layers, with these connections modeled by conductance-based formulations with a full set of cellular and synaptic parameters. For example, a detailed network model by Hennig et al. (Hennig et al. 2002) was used to test the influence of various retinal cell classes and subcircuits on the unique response pattern in each identified RGC type. Another model of the cone-horizontal cell network was used to study the biological origin of recorded damped oscillations in the retinal network (Tsai et al. 2017).

More recently, a discrete-neuronal network model was used to study the effects of electrical stimulation in the degenerated retina (Loizos et al. 2018). In this model, the retina was degenerated

by simulating anatomical and functional remodeling which occurs in the early stages of retinal degeneration. The deceased retinal network connectivity was based on high-speed automated electron optical images recorded from animal models (Marc et al. 2013).

It is important to note that detailed morphologically realistic models are not typically used for discrete-neuronal network modeling, mainly due to computational efficiency, except in those studies focusing on local microcircuit stimulation. Examples of the latter include (1) ionic models of rod/cone photoreceptors, bipolar cells, amacrine cells, and RGCs in an accurate network retinal description (Publio et al. 2009); (2) morphological-detailed RGC and bipolar layers in a computational model of retinal degeneration (Loizos et al. 2018); (3) a morphological RGC model in a local bipolar-RGC circuit (Resatz and Rattay 2004; Rattay and Resatz 2004); and (4) a recent model of the RGC layer represented by morphologically realistic models with dendrodendritic gap junctions (Publio et al. 2012).

Continuum Models

Continuum models (see Fig. 1, type V) have been used to simulate the response of bulk retinal tissue activation in an averaged spatial sense, without explicit representation of the constituent neurons. Continuum bidomain (intra- and extracellular domains) formulations have been proven useful in cardiac (Roth and Wikswo 1994; Henriquez 1993) and neural tissue simulation (Altman and Plonsey 1990; Martinek et al. 2008). These models are able to simulate bulk active or passive current flow across neuronal membranes into the extracellular space, perturbing the extracellular potential, as has been observed experimentally dating back several decades (Brindley 1956). This advantage allows the continuum bidomain approach to be an ideal tool for simulating the spatial extent of retinal activation due to extracellular electrical stimulation, as well as investigate the influence of electrode configuration, position, and stimulus parameters on retinal tissue responses.

In continuum retinal models, the dynamics of both extracellular and intracellular potentials are considered:

$$\begin{aligned} J_m &= \nabla \cdot \left(-\frac{r\sigma_e}{2} \nabla V_e \right) = \nabla \cdot \left(\frac{r\sigma_i}{2} \nabla V_i \right) \\ &= C_m \frac{\partial V_m}{\partial t} + J_{\text{ion}} \end{aligned} \quad (9)$$

where $V_m = V_i - V_e$ and σ_e is the extracellular conductivity. Some formulations adopt a “pseudo-bidomain” approach (Yin et al. 2010), by tying the intracellular potential to a remote resting potential:

$$J_m = \nabla \cdot \left(-\frac{r\sigma_e}{2} \nabla V_e \right) = g_r (V_r - V_i) \quad (10)$$

where V_r is the intracellular potential of a “remote” neural compartment and g_r is an intracellular conductance tying the intracellular potential to this remote compartment. The effect of the latter parameter is to prevent the intracellular potential from floating freely with changing extracellular potential, due to an applied stimulus.

The first such description of retinal electric simulation was the Dokos et al. (2005) model, comprising a vitreous and an active RGC layer (Dokos et al. 2005). It represented a “genuine bidomain” formulation (i.e., Eq. (9)) and was used to simulate the retinal response to a bipolar electrode configuration using various stimulus waveforms. This model was then extended by adding further retinal layers, including a passive inner plexiform layer, nuclear layer, subretinal space, retinal pigment epithelium, and choroid (Joarder et al. 2011). A similar model was also used to investigate the threshold of neuronal activation and the spatial extent of activation, thus providing valuable information regarding stimulus thresholds and localization of activation (Abramian et al. 2011). The subsequent retinal model by Abramian et al. was used to investigate multielectrode array stimulation (Abramian et al. 2014). This model examined the advantages of the so-called “quasi-monopolar” stimulation compared to bipolar or monopolar stimulation, combining the low thresholds of monopolar

stimulations with the focal spatial activation of hexapolar configurations (Matteucci et al. 2013).

Continuum models can be also be further extended by adding network effects, as in the retinal model of Yin et al. (Yin et al. 2010) which included excitatory input from bipolar cells and inhibitory input from wide-field amacrine cells. This model was subsequently refined by adding a dendritic compartment and synaptic currents to account for presynaptic influences on RGC activation (Al Abed et al. 2013). A further model utilizing microcircuitry of the ON cone pathway was formulated to investigate the network response to large and small spots of light (Yin et al. 2011).

These retinal models can be used to study the spatial activation profile of electrical stimulation. They provide a promising modeling framework which could be easily extended by incorporating newly identified ionic currents and synaptic connections. A more recent extension of the continuum approach was a multi-domain formulation to represent the major RGC compartments, including soma, dendrites, and AIS (Alqahtani et al. 2017).

Empirical Models of Retinal Function

Apart from the aforementioned biophysically detailed models, a black box approach may be used to represent the retinal network. The goal of these models is to capture statistical relationships between light stimuli and cell firing rates without describing detailed neural structure, biophysics, and network connectivity. A popular approach for implementing these block-structured models, also known as “cascaded models” (see Fig. 1, type VI), involves representing the retina as a series of linear and nonlinear temporal filter elements (Pillow et al. 2005, 2008). These models can closely reproduce responses of the retina to simple laboratory light stimuli using only a few free parameters. Empirical models do not attempt to accurately reconstruct biophysical aspects of real retinal neurons. However, they can provide enough overall functional characteristics to cover both the computational aspects of individual

retinal neurons and the collective capabilities of large-scale neural networks. They are thus very popular in modeling local neural circuits (Curlander and Marmarelis 1987), the larger retinal network (Teeters et al. 1997; Wohrer and Kornprobst 2009), or even the entire visual system (Halupka et al. 2017).

Empirical models of neural function were largely used to simulate behavioral characteristics of outer retinal neurons, the cones (van Hateren and Snippe 2007; Shah and Levine 1996a; Shah and Levine 1996b), and rods (Hamer et al. 2005; Lamb and Pugh 1992). Despite their high degree of simplicity, these phenomenological models have been successfully applied to investigate specific physiological mechanisms, including those underlying normal and abnormal rod-receptor activity affected by retinodegenerative disease (Hood et al. 1993), as well as nonlinear synaptic dynamics between photoreceptors and downstream neurons (Juusola et al. 1995).

In empirical models, the specific neural spiking behaviors were reproduced by their unique transfer functions, characterizing linear and nonlinear spatial summation mechanisms in various types of RGCs in the retina (Victor 1988, 1987). A generic spike-train simulator was also able to accurately reconstruct spiking responses in a large range of functionally identified RGCs from different species (Keat et al. 2001).

These functional models have also been popular for studying retinal motion detection and anticipation (Table 2). In one study, motion extrapolation in many species was reproduced by block structures representing the spatially extended receptive field, the biphasic temporal response, and a nonlinear contrast gain control (Berry et al. 1999). Another model of object motion-sensitive circuitry was able to predict the neuronal response at each stage of the circuit (Baccus et al. 2008), revealing the contribution of specific retinal interneurons in global motion detection.

However, the mechanisms underlying visual information processing can be far more complex than a series of temporal filters. Functional computation in a real retinal neuron is also highly related to its physical structure, ionic channel

Computational Models of Neural Retina, Table 2 Task-specific applications of various retinal neuron modes and the biological species each model is based on

Task	Biological species a model is based on

Electrical stimulation of retinal network	Tiger salamander cone, rabbit horizontal cell: (Tsai et al. 2017)

expressions, and synaptic interactions. In this regard, empirical models are not ideal for relating high-level response characteristics of neurons, or of a neural network, to the underlying mechanisms from which these characteristics arise. Although there have been a few examples of empirical models in simulating nonlinear interactions of multielectrode stimulation of the retina (Maturana et al. 2018) and visual cortex (Halupka et al. 2017), these models cannot easily simulate cellular responses to extracellular or intracellular electrical stimulation, limiting their utility in modeling retinal activation by artificial electric stimulation, as in the case of visual prostheses.

Outlook on Retinal Modeling

Among all retinal neuron types, the mechanisms underlying morphologically complex retinal neurons such as amacrine cells or RGCs are still unclear (for a review see Masland (2012)). There are more than 30 RGC types in the mammalian retina (Baden et al. 2016). A definitive description of these cells has not yet been made due to their rich diversity in both intrinsic electrophysiological and morphological properties. Limited experimental information on ion channel kinetics and distributions in identified cell types also makes cell-type-specific model parameter optimization a difficult task. Prior models of these neurons have been largely limited to identification of individual types, regardless of the diversity of the cellular morphology and membrane channel distributions/kinetics in each cellular region, despite the fact that the correlation between neuronal function and inherent biophysical properties is highly significant, as suggested by experimental studies (O'Brien et al. 2002; Wong et al. 2012). On the other hand, despite far less morphological diversity, there are still many debates about the functional classification and mechanisms of horizontal cells and bipolar cells. New knowledge about these “preprocessing” neurons continues to be found (Herrmann et al. 2011; Klaassen et al. 2011; Jackman et al. 2011; Freed 2000; Dreosti et al. 2011). Therefore, further model

validation based on newly found experimental evidence is still required to quantitatively identify and define these cells.

At the single-cell level, the composition of ion channels in retinal neuron models continues to be refined. The initial FCM model with five active membrane currents appears to be oversimplified, with the identification of new ionic channels in retinal neurons (Miller et al. 2002; Tabata and Ishida 1996; Lee and Ishida 2007). Ionic channel formulations are generally based on voltage clamp experimental data. The properties of these new currents and their regional distributions in different neuron types may significantly contribute to the overall neural response. With the likely discovery of more ionic mechanisms in retinal neurons, there still remains substantial room for improvement of the single-cell models.

In whole-retina models, the functional significance of cell morphology has not been systematically studied, despite of its importance being recognized in brain neuron network modeling (Traub et al. 2005). Why do retinal neurons present a large range of morphological diversity? It appears that morphological factors play some role in mediating neuronal function. Cell-specific morphological information will therefore play an increasing role in the development of future tissue or network-based models of retinal function.

Finally, the ability of existing retinal neuron models to reproduce experimental data under degenerative conditions is still unclear. Experimental studies (Chua et al. 2013; Kalloniatis et al. 2016; Nivison-Smith et al. 2013; Jones and Marc 2005) have shown that retinal neurons undergo remodeling in degenerative disease, leading to altered synaptic connections and neurotransmitter release, as well as functional changes (Cho et al. 2016). These retinal network changes will influence the RGC response to electrical stimulation. However, detailed biophysical mechanisms underlying retinal remodeling are still under debate (Trenholm and Awatramani 2015; Margolis and Detwiler 2011; Tsai et al. 2017). Thus, a computational model that can simulate critical stages

of retinal network remodeling during degenerative disease will be a major contribution to this area.

Computational Models of Neuromodulation

Angela J. Yu

Department of Cognitive Science, University of California, La Jolla, CA, USA

Definition

Neuromodulatory systems serve a special meta-processing role in the brain. Due to their anatomical privileges of having massively extensive arborization patterns throughout the central and peripheral nervous systems and to their physiological capacity of finely controlling how other neurons communicate with each other and plasticize, they are ideally positioned to regulate the way information is acquired, processed, utilized, and stored in the brain. As such, neuromodulation has been a fertile ground for computational models for neural information processing, which have strived to explain not only how the major neuromodulators coordinate to enable normal sensory, motor, and cognitive functions but also how dysfunctions arise in psychiatric and neurological conditions when these neuromodulatory systems are impaired.

Detailed Description

Although much still remains unknown or opaque about neuromodulatory functions, a computationally sophisticated and coherent picture is beginning to emerge on the back of recent modeling works (Dayan 2012). The four major neuromodulators that have received most theoretical treatment are dopamine, serotonin, acetylcholine, and norepinephrine. They all play important roles in regulating cortical functions such as inference, learning, and decision-making. Broadly speaking, dopamine and serotonin appear to be critical for the processing of stimuli and events with salient affective value, such as rewards and punishments, and the learning and execution of actions that lead to greater subjective utility (more rewards or fewer punishments); in contrast, acetylcholine and norepinephrine appear to be most critical for signaling various forms of uncertainty that plague cortical computations, arising from intrinsic neuronal processing noise, external environmental changeability, as well as imperfect sensory observations.

Reward and Punishment

One of the best understood computational functions of neuromodulation is the role of dopamine (DA) in signaling reward prediction errors (Montague et al. 1996; Schultz et al. 1997), associated with a reinforcement learning algorithm known as temporal difference learning (Sutton 1988), which can learn not only which stimuli predict future rewards but also the temporal delay until such a reward appears. Computational models have suggested reward prediction error to be important for at least three different functions. First, the most obvious, is the learning of environmental cues that predict future rewards as well as actions that lead to greater or lesser amount of reward. There is evidence that D1 dopamine receptors in the direct or “go” pathway in the striatum mediate the facilitation of actions with surprisingly good outcomes or positive prediction errors, whereas D2 dopamine receptors in the indirect or “no-go” pathway in the striatum

underlie the inhibition of actions that lead to negative prediction errors (Gerfen et al. 1990; Smith et al. 1998; Frank et al. 2004; Frank 2005; Cohen and Frank 2009; Kravitz et al. 2012). A second role suggested for dopamine, related to the theory of incentive salience (Berridge and Robinson 1998; McClure et al. 2003) and potentially via D1 receptors in the nucleus accumbens (Murschall and Hauber 2006; Frank 2005; Surmeier et al. 2007; Surmeier et al. 2010), is that it controls the expression of Pavlovian approach responses associated with the prospect of reward (Ikemoto and Panksepp 1999), in turn facilitating the initiation and learning of instrumental responses that boost reward (Satoh et al. 2003; Nakamura and Hikosaka 2006; Talmi et al. 2008). A third role suggested for the dopamine-mediated prediction error is that over the long term, the average prediction error reflects the average reward rate, which represents an opportunity cost that can drive the level of response vigor (Niv et al. 2007) or the trade-off between speed and accuracy (Dayanik and Yu 2012).

While animals need to seek out rewarding circumstances and actions, they also need to avoid punishing or threatening ones. The learning of avoidance behavior, or behavioral inhibition, appears to depend on both dopamine and serotonin (5-HT). Unexpected punishments (Ungless et al. 2004; Cohen et al. 2012) and the nondelivery of expected reward (Schultz et al. 1997) have both been shown to activate the dopaminergic system, which enable the learning of avoidance behavior via D2 receptors in the indirect pathway of the striatum (Frank et al. 2004; Kravitz et al. 2012). Complementing the dopaminergic system, serotonin has been suggested to play an opponent role, by signaling prediction errors associated with future “version” rather than reward (Deakin 1983; Daw et al. 2002; Cools 2011; Boureau and Dayan 2011). The suggestion is that initial hint of future aversion would activate the serotonergic prediction error (Schweimer and Ungless 2010) but that once the threat of that aversive outcome is avoided due to actions or circumstances, then the dopaminergic neurons would be activated by the associated reward prediction error, signaling safety, and thus reinforce the avoidance action

(Johnson et al. 2001; Moutoussis et al. 2008; Maia 2010). Aside from learning avoidance actions, serotonin has also been thought to be important for mitigating impulsivity and enabling general behavioral inhibition, such as delaying actions in order to receive a larger reward (Miyazaki et al. 2011; Doya 2002).

Uncertainty

Uncertainty of various forms plagues the brain's interactions with the environment. In a Bayesian statistical framework, optimal inference and prediction, based on unreliable observations in changing contexts, require the representation and utilization of different forms of uncertainty. For example, in the context of multimodal cue integration, uncertainty about the state of the world induced by unreliability of a cue should lead to the relative downgrading of that source of information relative to other more reliable cues (Ernst and Banks 2002; Battaglia et al. 2003). Analogously, in the context of integrating top-down and bottom-up information, uncertainty about the validity of an internal model of the environment should lead to relative suppression of top-down expectations in relation to bottom-up, novel sensory inputs (Yu and Dayan 2003; Körding and Wolpert 2004; Yu and Dayan 2005b). On the other hand, uncertainty about the predictive or other statistical properties of a stimulus or event should upregulate the *learning* accorded to that stimulus/event, relative to other better understood aspect of the environment (Yu and Dayan 2005b; Behrens et al. 2007; Nassar et al. 2012). Strictly speaking, exact Bayesian statistical computations need not distinguish among the various forms of uncertainty, as they are all reflected as probability distributions, or properties of distributions, of the relevant random variables under consideration. However, the brain can hardly be expected to implement arbitrarily precise and complex Bayesian computations, given its limited processing hardware, and thus needs to represent the most common and critical aspects of uncertainty so as to achieve near-optimal but efficient computations (Yu and Dayan 2003, 2005a, b).

Based on a wealth of physiological, pharmacological, and behavioral data implicating acetylcholine (ACh) and norepinephrine (NE) in specific aspects of a range of cognitive processes, it has been proposed that they respectively signal expected and unexpected uncertainty, with the former associated with known stochasticity or ignorance in the current environment and the latter arising from unexpected gross changes in the environment that require drastic revision of internal representation of the behavioral context (Yu and Dayan 2005b). The two forms of uncertainty are expected to be partly synergistic and partly antagonistic: a rise in unexpected uncertainty should lead to an increase of expected uncertainty (due to known ignorance), while expected uncertainty in turn has a suppressive influence on unexpected uncertainty, since the level of evidence for a fundamental change induced by a certain magnitude of prediction error should be normalized by the degree of expected variability (prediction error) (Yu and Dayan 2005b). Consistent with this, Sara and colleagues have found similarly antagonistic interactions between ACh and NE in a series of learning and memory studies (Sara 1989; Ammassari-Teule et al. 1991; Sara et al. 1992; Dyon-Laurent et al. 1993, 1994). They demonstrated that learning and memory deficits caused by cholinergic lesions can be alleviated by the administration of clonidine (Sara 1989; Ammassari-Teule et al. 1991; Sara et al. 1992; Dyon-Laurent et al. 1993, 1994), a noradrenergic α -2 agonist that decreases the level of NE (Coull et al. 1997).

In recent years, a number of experimental studies have confirmed major aspects of the uncertainty-based account of acetylcholine and norepinephrine functions. Pupil diameter, known to be correlated with noradrenergic neuronal activation level (Aston-Jones and Cohen 2005), has been shown to be, on the one hand, correlated with the discarding of previous beliefs and strategies and the exploration of novel ones (Gilzenrat et al. 2010; Jepma and Nieuwenhuis 2011) and, on the other hand, reflective of subjects' unexpected uncertainty beyond predicted variability (Preusschoff et al. 2011). Moreover, there is evidence that pupil

diameter is reflective of unexpected uncertainty (operationalized here as change point probability) and accompanies the discarding of previous beliefs and the incorporation of new data into a novel belief state (Nassar et al. 2012). Interestingly, pupil dilation is controlled by two muscles, the sphincter for contraction and the dilator for dilation, which are respectively innervated by acetylcholine and norepinephrine (Hutchins and Corbett 1997). The administration of cholinergic antagonists, scopolamine (muscarinic) and mecamylamine (nicotinic), increases pupil size in normal elderly volunteers (Little et al. 1998). Moreover, Alzheimer's disease (AD) patients, who have a severe and specific cholinergic deficit, have larger pupil size than controls both tonically and in response to light, while AD patients medicated with acetylcholinesterase inhibitor, which increases the endogenous level of acetylcholine, show a pupil response much closer to controls (Fotiou et al. 2009). This raises the intriguing possibility that the pupil dilation results might reflect the joint influence of both norepinephrine and acetylcholine. Separately, pharmacological and lesion studies directly manipulating acetylcholine levels have also produced behavioral results consistent with the cholinergic expected uncertainty hypothesis (Thiel and Fink 2008; Córdova and Chiba 2004).

Definition

Deep brain stimulation is a surgical therapy involving electrical stimulation of the brain via chronically implanted electrodes.

Once implanted, there are a number of stimulation parameters which must be set by the clinician in order to suppress the pathological symptoms, while not inducing any unwanted side effects.

Computational models can be used to estimate the optimal parameter settings for DBS to aid this process.

Detailed Description

Deep Brain Stimulation

Over 20 years ago (Benabid et al. 1987), deep brain stimulation (DBS) was introduced as a clinical therapy for a number of neurological and more recently psychological disorders. The treatment involves chronic electrical stimulation via quadripolar electrodes implanted into various regions of the human brain in a disorder-specific manner. Most commonly, DBS is used to treat a range of movement disorders such as essential tremor, Parkinson's disease, and dystonia (Vidailhet et al. 2005; Deuschl et al. 2006; Kupsch et al. 2006), with electrodes typically implanted into regions of the thalamus or the basal ganglia.

The treatment works well, and 70–80% of patients experience benefit from the treatment (Parkinson's UK).

Parameter Settings

Despite the success of the treatment, however, there remains a lack of understanding of how this electrical current changes neuronal activity to lead to the observed therapeutic benefits (Benabid 2007; Kringelbach et al. 2007). This lack of understanding in turn restricts the clinical efficacy of DBS, further development of the technology, and identification of novel clinical applications. Of particular importance to the patient and clinician, however, is the identification of the optimal set of parameters for stimulation. These parameters include stimulation frequency, pulse width, amplitude, and contact configuration (see Fig. 1). This process of parameter selection for an individual patient is time consuming and difficult (Rizzone et al. 2001; Moro et al. 2002; Kuncel and Grill 2004), relying mostly on trial and error and the intuition of an experienced clinician. If we knew how DBS was achieving the clinical improvement at the neuronal level, patients' symptoms could be better targeted.

FEM Models

In recent years, computational models have been used to investigate this issue (Wei and Grill 2005; Yousif and Liu 2009; Butson et al. 2011) via a two-step approach: first, the spread of the electric field is modelled in a 3-dimensional model of the electrode and the surrounding tissue in a finite element method (FEM) model (Fig. 2a). The potential distribution induced by stimulation can then be calculated by solving the Laplace equation within the geometry.

Neuronal Models

For the second step, the electric field estimation is applied to a model of neuronal structures (Fig. 2b) to predict the effect that stimulation has on the

Computational Models Supporting Parameter Finding for Deep Brain Stimulation, Fig. 1 Once the quadripolar DBS electrodes are implanted, an optimal set of parameters must be chosen by the clinician. The three parameters are stimulation frequency, pulse width, and amplitude of the waveform. In addition, the electrode can

be configured in different ways. If monopolar stimulation is selected, a single contact is used as the cathode, and the case of the stimulator, which is usually implanted in the chest, is used as the return electrode. If bipolar stimulation is selected, two contacts are used, and a near-field dipole is created

Computational Models Supporting Parameter Finding for Deep Brain Stimulation, Fig. 2 To model the impact of DBS on the human brain, a two-step approach is typically taken. (a) The geometry of interest is modelled in 3-dimensions and the equation of interest solved over this geometry to give a potential distribution (schematized here in color). (b) This potential distribution can then be applied to a dynamic model of neural activity, typically axons or neurons

firing properties in the surrounding tissue. At present, the vast majority of such models focus on arrays of unconnected axons, but recent work has shown that by modelling single neurons and networks of neurons, we can observe subtle effects of DBS on neural activity which would be overlooked by axon models (Yousif et al. 2010, 2012a, b). It has also been shown that using neuron models compared to axon models predicts that a much

smaller region of surrounding tissue will be activated, which will clearly impact on the use of such models for predicting parameter settings.

Making Predictions

Previously, there have been attempts to link the predictions made by FEM models to clinical

studies or observations (Butson and McIntyre 2007; Frankemolle et al. 2010; Chaturvedi et al. 2010). Similarly a limited amount of work has been done in order to link model results to measurements of the electric field in the macaque brain (Miocinovic et al. 2009). This not only allows the correlation of results with the observed clinical improvement but can also constrain the model parameters as the DBS-induced electric field can be directly measured. This process of validation is crucial for the success of these models in aiding the understanding of DBS and for establishing their credibility to clinicians who will ideally use such models in clinical practice.

In recent work, the use of such models to visualize the impact of specific parameter settings for an individual patient has emerged. Yousif et al. reported a clinical case where a bipolar setting was not tolerated by a patient with essential tremor during the first DBS programming session (Yousif et al. 2012). However, when the polarity of the same two contacts was reversed, the patient was able to tolerate a 70% increase in amplitude. By utilizing a computational modelling approach to visualize the effect of the two settings on the firing of neural fibers, it was possible to confirm that reversing the polarity, stimulated fibers of the nearby internal capsule. Stimulation of this fiber bundle has been reported to induce side effects from a thalamic electrode (Limousin et al. 1999). Hence, such an approach was used to help the clinician to understand why one configuration was superior to another, when simple consideration of the electric field induced by each would indicate them to be equivalent.

Future work should take a prospective approach to parameter settings. For each patient that is treated with DBS, an anatomically accurate model of the current spread can be produced and coupled to axon and/or neuron models. Prior to the process of clinically finding parameters, such a model can then be simulated at different parameter settings, to maximally activate axons or change the firing rate of neurons within the target brain structure. In this way, a set of parameters can be found which will guide the clinician's search for the optimal set of parameters. Such systems have now started to emerge from commercial

companies. In conclusion, such a method which theoretically predicts a set of parameters would streamline the process, reduce the stress and discomfort to patients and reduce the time required for tuning, checking, and adjusting parameters.

Definition

A computational model used to optimize electrodes and waveforms for deep brain stimulation (DBS) is typically composed of two separate models: a volume conductor model of an electrode in brain tissue used to calculate electrical potential distributions and cable models of neural elements (e.g., axons, local cells) used to calculate the response of neurons to the imposed stimulation. The integrated model is interfaced with an optimization algorithm to search for solutions that

increase the performance of DBS, where performance could be related to the efficiency, selectivity, and/or safety of stimulation. The results from the two models are combined to evaluate a specified cost function, and the optimization algorithm searches for a set of parameters that minimize the cost.

Detailed Description

DBS is an established therapy for treating neurological disorders, in which an implanted array of cylindrical electrodes is used to deliver rectangular waveforms of electrical pulses to specific regions of the brain. Trial and error experimentation is not an efficient approach to design improved electrodes or waveforms and is unlikely to lead to an optimal result. Therefore, model-based design is being used to develop improved DBS electrodes (Butson and McIntyre 2006; Keane et al. 2012) and waveforms (Sahin and Tie 2007; Yousif et al. 2008; Foutz and McIntyre 2010; Wongsarnpigoon and Grill 2010).

Parameterization of Electrodes and Waveforms

There are an infinite number of possible electrode designs and waveform shapes. In real DBS systems, however, practical limitations exist, such as limitations on the size and number of electrodes and the maximum rate of change (slew rate) of the output voltage in the implantable stimulator. Therefore, the choice of parameterization should define as large a number of electrodes or waveforms as possible using the least number of parameters while keeping practical limitations in mind. Figure 1 gives an example.

Volume Conductor Models of Electrodes in Brain Tissue

The first step in the optimization process is calculating the electric field ($\vec{E}$) generated by the

Computational Models to Optimize the Electrodes and Waveforms for Deep Brain Stimulation,

Fig. 1 Parameterization of an electrode (array) and waveform. An individual cylindrical electrode (*left*) can be parameterized by its radius (r), height (h), and the fraction of its surface that is conductive (f). In addition, the configuration

of the array (*middle*) can be parameterized by the positions of the individual electrodes along the shaft ($z_1 - z_3$). Waveforms (of voltage or current) applied to each contact – or between contacts – can be parameterized either by using the coefficients of a number of splines to define the waveform (*right*) or by discretizing the waveform into a finite time series

passage of current through brain tissue. Although the electrical properties of brain tissue vary with frequency, it is valid to assume that the capacitive, inductive, and wave propagation effects can be ignored for typical DBS parameters (Bossetti et al. 2008). Under quasi-static conditions, brain tissue can be treated as purely resistive, and $\vec{E}$ is derived from the gradient (∇) of the scalar potentials (Φ):

$$\vec{E} = -\nabla\Phi \quad (1)$$

It is also valid to assume that the resistivity (ρ) of brain tissue is linear or independent of Φ (Nicholson and Freeman 1975). Therefore, $\vec{E}$ is directly proportional to the current density distribution ($\vec{J}$):

$$\vec{E} = \rho \cdot \vec{J} \quad (2)$$

Substitution of Eq. 2 – Ohm's law – into Eq. 1 and taking the divergence of the result yields Poisson's equation:

$$\nabla^2\Phi = -\nabla \cdot (\rho \cdot \vec{J}) \quad (3)$$

which is the partial differential equation solved in the forward field problem for DBS.

The electrical properties of brain tissue are highly inhomogeneous (position dependent) and

anisotropic (direction dependent). Therefore, Poisson's equation cannot be solved analytically, and numerical methods are required to approximate a solution. The finite element method (FEM) is the preferred choice for modeling DBS because it can be readily applied to the complex geometries of the brain. For example, patient-specific FEM models are the current state of the art: The geometries of brain structures are defined by individual brain images, and the tensor conductivities of each brain region are determined using diffusion-tensor magnetic resonance imaging (Butson et al. 2007; Chaturvedi et al. 2010). Patient-specific models show good agreement with clinical results, but this performance comes at the expense of complexity and associated computational time.

In cases where an iterative optimization process requires solving Poisson's equation hundreds to thousands of times, simplified analytic and semi-analytic solutions offer a compromise between the predictive capabilities of the model and computational time. For example, if brain tissue is approximated as an infinite homogeneous medium with a single bulk ρ , then cylindrical harmonics (i.e., Bessel functions) can be used to calculate semi-analytically the potentials generated by the DBS electrode array. Although this method requires solving a system of unknowns, it can still be used to evaluate the effect of the electrode geometry on Φ . However, if electrode

geometry is not important and only the temporal dynamics matter, then the DBS electrode can be approximated as a point source of current (Zhang and Grill 2010), which yields the following analytic solution (Li and Uren 1998):

$$\Phi(x, y, z) = \frac{\|p_{i,j}\|^{1/2}}{4\pi(\rho_{11}x^2 + \rho_{22}y^2 + \rho_{33}z^2 + \rho_{11}x^2y^4 + \rho_{1,3}^{yz+\rho_{23}}yz)^{1/2}} \quad (4)$$

where I is the stimulus current, $\| \cdot \|$ is the determinant operator, $\rho_{i,j}$ is the resistivity tensor, and x, y , and z are the spatial coordinates relative to the point source (4) minimizes computational time and can be combined with the method of images to account for simple inhomogeneities in the brain tissue.

Cable Models of Neural Elements

The second step in the optimization process is simulating the response of target neural elements to the electric potentials calculated with the volume conductor model. Axons and dendrites are much longer than they are wide and azimuthally symmetric about their longitudinal axis, so they are modeled as a one-dimensional cable of cylindrical membrane compartments, each with circuit elements modeling the membrane and axoplasm. If the soma is also approximated as a series of cylindrical compartments, then the flow of charge through the entire neuron can be described using the cable equation (Fig. 2). The cable equation can be solved numerically using the finite difference method (Carnevale and Hines 1997).

Optimization Algorithms

The final step in the optimization process is using the results from the computational model of DBS to evaluate and minimize a cost function via a numerical optimization algorithm. The choice of cost function depends on the goal of the optimization. If the goal is to extend the battery life of the

Computational Models to Optimize the Electrodes and Waveforms for Deep Brain Stimulation, Fig. 2 Modeling neural elements with the cable equation.

An isolated patch of membrane on a neuron (*top*) is modeled using a one-dimensional cable (*middle*). In that cable, the flow of charge is quantified using the cable equation (*bottom*), where V_m is the membrane voltage, V_r is the resting voltage, R_m is the membrane resistance, C_m is the membrane capacitance, R_a is the axoplasmic resistance, Φ_e is the external potential, and n denotes the index of the compartment

device, efficiency is increased by minimizing the transferred electrical energy (E):

$$E = \int IVdt, \quad (5)$$

where I and V are the applied voltage and applied current, respectively. If the goal is to reduce the risk of tissue damage, then the injected charge (Q),

$$Q = \int Idt, \quad (6)$$

is minimized because Q is correlated with tissue injury (McCreery et al. 1990; Shannon 1992). Or, if the goal is to mitigate the sensitivity of clinical outcomes to the malposition of the electrode, selectivity is increased by constructing a curve, $p(x)$, of the proportion of a nontarget population activated versus selected proportions of a target population and minimizing the area (A) under the curve:

$$A = \int p(x) dx \quad (7)$$

The cost function must be minimized numerically, as there is no guarantee that it will be continuously differentiable over the parameter space defining the electrode and/or waveform. Using iterative methods (e.g., Newton's method and conjugate gradient) to minimize cost is impractical because they require approximating a Jacobian and/or Hessian, which may or may not exist for all space. Therefore, stochastic search algorithms are used to identify solutions that minimize cost, including simulated annealing, genetic algorithm, and particle swarm – inspired by the natural processes of crystallization, evolution, and the collective behavior of self-organized systems, respectively.

Optimal Electrodes and Waveforms

Computational studies of DBS show that rectangular waveforms are the most energy efficient for pulse widths (PWs) $\leq 40 \mu s$ (Sahin and Tie 2007). For all other PWs, Gaussian waveforms and triangular waveforms are the most energy efficient; and the PW that minimizes E depends on a number of factors, including the spatiotemporal distribution of the potentials and the geometry, position, orientation, and electrophysiology of the target neural element (Foutz and McIntyre 2010; Wongsarnpigoon and Grill 2010).

Although little work has been done on optimizing electrodes for DBS, emerging work shows that the same factors that impact waveform efficiency (see above) are also important in designing more efficient and selective electrode geometries (Howell and Grill 2013).

Computational Olfaction

Christiane Linster

Computational Physiology Lab, Department of Neurobiology and Behavior, Cornell University, Ithaca, NY, USA

Definition

In natural environments, airborne chemical stimuli are distributed unpredictably in time and space, and odorants from innumerable sources intermix freely. The olfactory system must perform computations to detect potential signals of interest within these noisy signals, extract these signals, form representations, compare these to those of previously experienced, differentiate relevant from irrelevant stimuli, and cue an appropriate response. Computational modeling suggests that subnetworks of the olfactory system may be dedicated to perform specific computations underlying these functions.

Detailed Description

Neural Networks Involved in Olfactory Computation

Computational models of the olfactory system have contributed immensely to the framing of experimental problems and the construction of complex hypotheses regarding its function. Computational models from detailed biophysical to large-scale simple neuron models have proposed how olfactory networks compute the functions necessary to extract and recognize important chemical signals.

Signal-to-noise ratio in the olfactory system is inherently low at the level of olfactory sensory neurons (OSN), which are broadly tuned to odorants. OSNs sharing a common response profile to odorants project their axons to specific glomeruli within the olfactory bulb (Mombaerts et al. 1996), with a very high convergence. This high

convergence ratio has been proposed to improve the signal-to-noise ratio during odorant detection (van Drongelen et al. 1978).

Mitral cells, along with middle and deep tufted cells, are the principal output neurons of the olfactory bulb. They are directly postsynaptic to OSNs and as such the pattern of mitral/tufted cell activation across the bulb constitutes the output representations. Besides input from a single class of OSNs, mitral/tufted activation pattern also depends on the activity of several classes of bulbar interneurons. For example, some form of *normalization of stimulus concentrations* is clearly evident in the concentration-response profiles of mitral cells; this function has been proposed to be the role of an extensive network of excitatory and inhibitory neurons in the glomerular layer (Cleland et al. 2007). *Contrast enhancement*, the effects of which have been directly observed in the olfactory bulb (Yokoi et al. 1995), can be functionally defined as a process of competition between neurons expressing similar response profiles. Simplified models of the olfactory system have been able to implement contrast enhancement using lateral inhibition between glomeruli (Cleland and Linster 2002; Linster and Cleland 2001; Linster and Gervais 1996; Linster and Hasselmo 1997, 1999; Linster and Smith 1997). Alternatively to these highly simplified representations, non-topographical models of contrast enhancement are also capable of distributing inhibition in proportion to receptive field similarity but use local computations and broad feedback inhibition to create contrast (Cleland and Sethupathy 2004).

The net activation of mitral cells is then translated into trains of action potentials, the precise *timing* of which appears to be regulated by coordinated *oscillations* measurable in field recordings across the OB. These bulbar oscillations are thought to depend on an extensive excitatory-inhibitory network of mitral cell secondary dendrites and granule cell interneurons, as well as reciprocal cortical connections that modulate bulbar activity according to behavioral state (Kay 2003; Lagier et al. 2004; Martin et al. 2004;

Ravel et al. 2003). Mitral cell spike synchronization patterns can mediate a second level of feature extraction to the odor representation (David et al. 2009), as follower neurons in diverse central olfactory structures (Linster and Cleland 2003) process incoming mitral cell spikes via synaptic learning rules, the best known of which rely upon precise spike timing (Cleland and Linster 2002; Song et al. 2000). The mechanisms of oscillations have been the focus of a number of computational modeling efforts, some proposing oscillators governed by an excitatory-inhibitory feedback loop, others proposing intrinsic oscillations in mitral cells synchronized by slow common inhibitory inputs (Bathellier et al. 2006, 2008; David et al. 2009; Erdi et al. 1993; Freeman 1987; Li and Hopfield 1989).

Even though some models propose *associative memory* functions for olfactory bulb (Erdi et al. 1993; Hendin et al. 1998), olfactory associative memory functions have been more commonly attributed to the piriform cortex, one of the targets of mitral cell axons projecting from the olfactory bulb. Specifically, the piriform cortex has been proposed to mediate the associative memory functions necessary for odor-context learning (de Almeida et al. 2013; Haberly 2001; Haberly and Bower 1989; Hasselmo et al. 1990) and hierarchical clustering (Ambros-Ingerson et al. 1990). For example, cortical short-term synaptic depression can be employed to filter out stable background odorants, whereas long-term synaptic plasticity can store associations between neurons responding to the same odor stimuli. Indeed, the extensive intrinsic feedback network in this cortex and its integration with afferent inputs closely resembles the structure of traditional theoretical associative memory networks as first described by Marr (Marr 1971).

Conclusions

Computational models have an established and growing role within systems neuroscience. As our understanding of neural processing and

interactions becomes more sophisticated, computer models of these systems are increasingly necessary in order to understand and interpret experimental results. In the olfactory system in particular, computational modeling will no doubt be essential to understanding the integration of the many factors influencing the construction and transformation of odor representations.

Definition

Computational psychiatry is a heterogeneous field at the intersection of computational neuroscience and psychiatry. Incorporating methods from psychiatry, psychology, neuroscience, behavioral economics, and machine learning, computational psychiatry focuses on building mathematical models of neural or cognitive phenomena relevant to psychiatric diseases. The models span a wide range – from biologically detailed models of neurons or networks to abstract models describing high-level cognitive abilities of an organism. Psychiatric diseases are conceptualized either as an extreme of normal function or as a consequence of alterations in parts of the model.

As in computational neuroscience more generally, the building of models forces key concepts to be made concrete and hidden assumptions to be made explicit. One critical function of these models in the setting of psychiatry is their ability to bridge between low-level biological and high-level cognitive features. While many neurobiological alterations are known, the exclusively atheoretical focus of standard psychiatric nosology on high-level symptoms has as yet prevented an integration of these bodies of knowledge. David Marr pointed out that models at different levels of description may be independent (Marr 1982). Nevertheless, algorithmic details may constrain functions at the computational level. The models used in computational psychiatry make these constraints explicit and thereby aim to provide normative conduits between the different levels at which neural systems are analyzed (Stephan et al. 2006; Huys et al. 2011; Hasler 2012; Montague et al. 2012). This in turn allows for a principled approach to study dysfunctions and indeed may allow the dysfunctions observed in psychiatry to inform neuroscience in general.

Practically, it underpins hopes that computational techniques may facilitate the development of a psychiatric nomenclature based on an understanding of the underlying neuroscience. Computational models enhance experimental designs by allowing more intricate neural and/or cognitive processes to be inferred from complex features of the data, often via Bayesian inference. These aspects motivate hopes that it may facilitate the development of clinical treatment and decision tools informed by advances in neuroscience.

Detailed Description

This entry describes four types of models applied to psychiatric diseases. The earliest models were connectionist (McClelland et al. 1986) or dynamical (King et al. 1984) and emphasized properties of the brain as a neural network. The second,

and now most common, class is models of reinforcement learning (Montague et al. 1996; Schultz et al. 1997; Sutton and Barto 1998). The third and fourth classes emphasize explicit model-based planning or social cognitive processes, respectively.

Connectionist and Neural Network Models

Connectionist approaches model psychological functions using a neural network in which particular neurons take on specific computational roles, for instance, representing a sensory input. Key aspects of the neural networks are based on particular features derived from biology (or known to be involved in psychopathology). This allows the consequences of these features for complex computation to be probed and hence is one direct approach to examining the link between Marr's levels. In psychiatry, connectionist models have been prominently applied to schizophrenia.

Patients with schizophrenia or mania can characteristically display rapidly changing, loose associations in their speech. Early work examined how parameters governing the dynamics of associative networks might reproduce this. An increase in noise, corresponding to a decrease in the dynamic gain, led to less specific memories, mirroring a broadening of associations in schizophrenia, and less stable, constantly altering memories, possibly mirroring the pressure of speech observed in mania. Spurious memories reminiscent of hallucinations arose when overloading the network with memories beyond its capacity (Grossberg and Pepe 1970; Hoffman 1987).

Patients with schizophrenia also show impairments in cognitive flexibility and control tasks that require the inhibition of a prepotent response. Cohen et al. (1996) used a connectionist network partitioned into four modules to model this. One module represented stimuli, another other responses, and a third the prefrontal cortex. A fourth module integrated the inputs from all

modules. The prefrontal cortex had a critical function in maintaining representations of task-relevant variables. When this memory function was impaired by a reduction in its gain, the network could accurately capture the impairments in performance seen in schizophrenia. As the gain was thought to depend on dopaminergic input, this work correctly predicted a prefrontal reduction of dopamine in schizophrenia. Later work further refined the role of dopamine in gating of information into the prefrontal cortex (Braver et al. 1999; Frank 2005).

Many psychiatric disorders are relapsing-remitting, with periods of well-being punctuated by times of illness. This is prominent in bipolar disorder, which can cycle rapidly between phases of depression and mania. Conversely, loss of diurnal sleep-wake rhythms is also common. These phenomena can be described by dynamical systems models of neural networks with feedback loops and delays interacting to produce oscillatory phenomena at various timescales (Mackey and Milton 1987; Milton 2010). The complexities of the local circuit, with synthesis, breakdown, and reuptake, can add substantial further complexity and facilitate the emergence of highly variable, chaotic solutions potentially relevant to multiple disorders (King et al. 1984).

Reinforcement Learning Models

Reinforcement learning (RL; Sutton and Barto 1998) describes a set of techniques aimed at choosing that action which maximizes the long-term expected reward. In terms of applications to psychiatric diseases, it is useful to differentiate between two approaches to solving this problem (Daw et al. 2005): a model-based and a model-free one. In the *model-based* approaches, the agent has a model $\mathcal{M}$ of the world that describes the consequences of actions and the desirability of the consequences. For instance, a player may know the rules of chess. The best move can then be inferred by considering all moves, their consequences, and the subsequent moves iteratively.

For most problems of interest, this model-based decision procedure is computationally unachievable. *Model-free* approaches replace computation by experience, maintaining a lookup table $Q(s, a)$ of the expected reward (and hence goodness) of each behavior a in situation s . This can be iteratively updated online with new experience by computing a prediction error (PE) δ which compares the obtained with the expected future reward $Q(s, a)$. This expectation $Q(s, a)$ can then be updated by letting $Q(s, a) \leftarrow Q(s, a) + \epsilon \delta$, where $0 \leq \epsilon \leq 1$ is a learning rate that determines how rapidly the qualities are allowed to change over time. That is, rather than inferring decisions from an understanding of the world, model-free choices are the result of repeated trial-and-error learning. This motivates the characterization of habits as model-free (Daw et al. 2005). Seminal work has shown that phasic signals by dopaminergic neurons are proportional to this PE δ (Montague et al. 1996; Schultz et al. 1997).

The application of reinforcement learning models to psychiatric diseases is motivated by a trio of facts. First, decisions are central to psychiatric disorders, and reinforcement learning techniques allow for a principled approach to decision-making. Decisions are the final common pathway preceding many aberrant behaviors, and poor decisions can have profound consequences for affected individuals. For instance, around a third of the life stress associated with major depressive disorder is due to poor decisions by individuals (Kendler et al. 1999). Second, many psychoactive substances and clinically useful medications influence neuromodulators: dopamine (antipsychotics such as haloperidol or clozapine and stimulants such as methylphenidate), serotonin (selective serotonin reuptake inhibitors, tricyclic antidepressants), noradrenaline (tricyclic antidepressants, serotonin-noradrenaline reuptake inhibitors), or acetylcholine (certain antipsychotics, cholinesterase inhibitors). Third, and unifying the first two, these same neuromodulators are central to computational models of decision-making. This is particularly clear for phasic

dopamine, which appears to report a signal akin to the PE δ used for learning in model-free RL (Montague et al. 1996; Schultz et al. 1997; Sutton and Barto 1998).

Predominantly Model-Free RL Accounts of Psychiatric Diseases

The simplest application of reinforcement learning models is in examining anhedonia, a central component of *depression*. Anhedonia describes a reduced ability to experience pleasure and is usually measured by verbal reports. People who report such a lack of pleasure are less likely to choose the more rewarding stimulus in a variety of standard learning (Costello 1972; Henriques et al. 1994; Pizzagalli et al. 2005) and stimulus reactivity (Bylsma et al. 2008) tasks. Decisions in some of these tasks can be captured by simple model-free reinforcement learning. Depression interferes with this learning by reducing the PE signal δ (Steele et al. 2007; Kumar et al. 2008; Chase et al. 2010a, b; Gradin et al. 2011), leading to reduced expectations of rewards over time. The PE δ is composed of the difference between expected reward and obtained reward, and anhedonia appears to reduce the former, while alterations of tonic dopamine affect the latter (Chowdhury et al. 2013; Huys et al. 2013).

Addictive substances release dopamine either directly or indirectly and modify dopamine receptors chronically (Volkow et al. 2009). This might simply suggest that addictive substances thereby result in overly large values of the drug-taking action by adding an irreducible floor to the PE signal δ . This would result in a persistent signal for learning, increasing the value of drug-taking actions without bound (Redish 2004; Dayan 2009). Other reinforcement learning models address the transformation from hedonic to compulsive drug taking (Everitt and Robbins 2005) by emphasizing the difference between model-free and model-based reinforcement learning (Redish et al. 2008). Drugs of abuse are known to lead to a

shift toward habitual behavior (Dickinson et al. 2000; Nelson and Killcross 2006), which can be captured by a shift from model-based to model-free decision-making (Daw et al. 2005). Neurobiologically, this shift might be accompanied by a progressive engraining of drug-taking actions through progressively more dorsal corticostriatal loops (Belin and Everitt 2008) and impairments of orbitofrontal function (Lucantonio et al. 2012).

Parkinson's disease is characterized by a progressive reduction of dopamine-producing cells in the midbrain and treated with dopamine precursors or agonists. Clinically, it results in a pronounced slowing (bradykinesia) and experimentally in facilitated learning of action omission compared to action production (no-go rather than go learning) that is normalized by dopaminergic medication. The effects of dopamine on *go* and *no-go* learning are accounted for by biologically detailed computational models of the basal ganglia (Frank 2005). Two critical structural aspects of the basal ganglia inform these models: (a) the presence of parallel corticobasal ganglia-thalamocortical loops for go and no-go learning and (b) the prevalence of activating D₁-type dopamine receptors on the go and inhibiting D₂-type receptors on the no-go loop (Maia and Frank 2011). Positive prediction errors are thus linked with go and negative prediction errors with no-go learning (Frank et al. 2007; Guitart-Masip et al. 2012). Such considerations are also relevant for *schizophrenia*, *Tourette's syndrome*, and *attention-deficit hyperactivity disorder* (Maia and Frank 2011). The work on Parkinson's disease is remarkable in that it has informed understanding of the function of the basal ganglia and dopamine in the healthy brain.

Finally, dopamine also plays a particular role in *schizophrenia* research because (a) the positive symptoms of psychosis respond to dopaminergic D₂ antagonists such as haloperidol (Seeman et al. 1976; Kapur et al. 2000; Laruelle et al. 2003) and because of (b) findings of increased dopamine synthesis, release, and synaptic levels in psychotic states (Heinz 2002; Kapur 2003) from the first

episode onward (Egerton et al. 2013). Model-free reinforcement learning models that link phasic dopamine to prediction error signals have been instrumental in relating the dopaminergic dysfunctions to cognitive phenomena. They have provided detailed accounts of the effects of dopamine manipulations on both learning and expression of learned contingencies in preclinical animal models such as the conditioned avoidance response and latent inhibition (Smith et al. 2004, 2005, 2007; Moutoussis et al. 2008). In humans, reinforcement learning models of decision-making have been combined with fMRI to examine the correlates of putatively dopaminergic PEs. Schizophrenia patients have a reduced response to prediction errors in striatal and midbrain regions (Juckel et al. 2006; Corlett et al. 2007; Jensen et al. 2008; Murray et al. 2008) that is normalized by treatment with second-generation antipsychotic medications (Juckel et al. 2006).

Passivity phenomena are another important characteristic feature of schizophrenia, where movements or sensations are experienced as not originating from oneself. Incorrect expectations about the consequences of one's own actions may lead to the assignment of the sensory consequences of one's own actions to external sources (Gray et al. 1991; Fletcher and Frith 2009). This may arise from an impaired connectivity between areas generating the predictions and those assessing the input (Ford et al. 2007), speaking to a generalized notion of PEs that is less directly related to phasic dopaminergic prediction errors (Rao and Ballard 1999) but rather to the consequences of dopamine in modulating synaptic plasticity (Friston and Frith 1995; Stephan et al. 2006; Friston 2008; Stephan et al. 2009).

Predominantly Model-Based Accounts of Psychiatric Diseases

Higher-level cognitive aspects of psychiatric diseases are captured by reinforcement learning models in which decisions are the product of searching an explicit model of the task at hand.

These have been applied to the concept of helplessness in depression, to the role of serotonin, and to delusional belief formation in schizophrenia.

In depression research, the concept of *helplessness* – a perception of lack of control – arose from animal behavior and describes animals who fail to escape from shocks after experiencing other stressors that were not under their control (Seligman and Maier 1967). Similar findings exist in humans (e.g., Miller and Seligman 1975). The simplest mathematical formulation of controllability is as a low action-outcome contingency $p(o|a)$ (Maier and Seligman 1976). More detailed accounts view controllability as relating not to individual available actions but to the average achievability of different outcomes by different choices of actions (Dayan and Huys 2009). This definition is close to the definition of control in control systems theory. The psychological construct whereby controllability is related to particular desirable outcomes can be captured by defining controllability as the fraction of rewards reliably achievable through appropriate action selection (Dayan and Huys 2009). These definitions of controllability can be used as prior beliefs and thereby account qualitatively for learned helplessness and chronic mild stress (Willner 1997) effects (Dayan and Huys 2009). Further refinements accounting specifically for generalization issues and for the computational costs of goal-directed decisions allow for more quantitatively detailed accounts (Lieder et al. 2013).

Serotonin plays an important role in research on depression because selective serotonin inhibitors (SSRIs) are first-line pharmacotherapeutic agents (Gelder et al. 2006) and because dietary manipulations that are thought to acutely reduce serotonin (acute tryptophan depletion) can lead to a rapid recurrence of symptoms in formerly depressed patients (Smith et al. 1997). However, animal work has related increased serotonin to behavioral inhibition, aversive expectations, and expression of helplessness (Soubrié 1986; Maier and Watkins 2005), suggesting that a reduction in serotonin should improve depressive symptoms.

Reinforcement learning models have linked the inefficient avoidance of negative events due to serotonin in a model-free system with an increased exposure to more negative events. These experiences might in turn underlie more negative moods due to serotonin reductions (Dayan and Huys 2008; Boureau and Dayan 2011; Dayan 2012). Further work has characterized the interaction of this model-free behavioral inhibition with internal cognitive planning models and has suggested that serotonin might also inhibit internal thought processes. This would be instrumental in facilitating planning by pruning overly large decision trees to a computationally manageable size (Huys et al. 2012). While serotonin is also central to helplessness, this computational relationship has not yet been examined.

“Jumping to conclusions” is a phenomenon that aims to capture *delusional belief formation*. It describes a tendency for patients with *paranoid ideation* to declare a strongly held belief based on data that should not be sufficient to warrant such strong beliefs (Garety et al. 2005). However, a model-based reinforcement learning model of the standard task used to measure jumping to conclusions (the “beads-in-a-jar” task) suggested that the reason patients with schizophrenia jumped to conclusions was not due to aberrantly strong beliefs but due to taking into account their future inability to exploit further data (Moutoussis et al. 2011).

Game-Theoretical Approaches to Social Dysfunction

Psychiatric disorders have a profoundly detrimental effect on social function. Social interactions are extremely complex and therefore difficult to investigate directly. Game-theoretical approaches allow interpersonal cognition to be probed parametrically because the social communication channel is highly restricted yet functional. Economic games benefit from having been extensively examined both theoretically and experimentally in economics (Camerer 2003).

Borderline personality disorder (BPD), which is characterized by unstable personal relationships and inappropriate emotional responses, leads to a breakdown of cooperation in *trust tasks*. In this task, the first participant (the investor) chooses which fraction of an endowment to invest. The investment is multiplied, and the trustee chooses what fraction of the multiplied amount to return to the investor. When played over multiple rounds, both players are best off when they cooperate (i.e., when the investor invests and the trustee faithfully returns a substantial fraction). However, this cooperation is easily broken. Healthy participants maintain cooperation by repairing lost trust through signals (e.g., by investing a large fraction to signal willingness to cooperate; King-Casas et al. 2005). Patients with BPD fail to recognize social signals used to repair social bonds after temporary ruptures, potentially due to a failure of the insula to respond (King-Casas et al. 2008). *Autistic spectrum disorder (ASD)* on the other hand does not affect the maintenance of cooperation in the trust task, but the cingulate cortex does not tag “self”-responses accurately (Tomlin et al. 2006; Chiu et al. 2008). In related cooperative games (e.g., the “stag hunt” game), ASD patients have a less rich representation of the other’s strategic abilities (Yoshida et al. 2008, 2010a, b). Responses of healthy volunteers to patients with a variety of psychiatric disorders in the trust task fall into distinguishable classes (Koshelev et al. 2010). This might allow the use of healthy volunteers as “biosensors” and formalizes one important aspect and use of empathy or even countertransference in psychiatric clinical practice. Formally, these tasks are partially observable Markov decision problems and can be modeled as such (Yoshida et al. 2008; Ray et al. 2009).

Limitations

Computational approaches to psychiatric disorders focus on decision-making, valuation, and cognition. While this is critical to many psychiatric disorders, immunological, endocrine, or

vegetative dysfunctions are so far largely beyond these accounts.

Acknowledgments I thank Dominik Bach, Kay H. Brodersen, Anthony Cruickshank, Peter Dayan, Marc Guitart-Masip, Helene Haker, Gregor Hasler, Falk Lieder, Tiago Maia, John Milton, Michael Moutoussis, Peggy Seriès, and Klaas Enno Stephan for informative comments and discussions on an earlier version of this contribution.

Definition

The term “conductance-based models of nonlinear dynamics in vertebrate motoneurons” refers to conductance-based motoneuron models that capture the complex nonlinear membrane

properties (e.g., bistability) of vertebrate motoneurons observed both in vivo and in vitro under certain conditions. Numerous conductance-based motoneuron models with widely varying morphological complexities and different ionic current composition exist that reproduce the experimentally observed nonlinear membrane properties. This article focuses on models that assume minimally required morphological complexity (e.g., two compartments) and ionic conductances. The resulting reduced set of equations and parameters describing such models have enabled detailed analyses of model behavior using geometric dynamical systems methods to provide insight into the basis of nonlinear membrane properties in vertebrate motoneurons.

Detailed Description

Dynamics of vertebrate motoneurons are phylogenetically conserved sharing common phenomenology from turtles to humans (Hornby et al. 2002). Under certain experimental conditions, these neurons display nonlinear membrane properties such as bistability (Bennett et al. 2001; Hounsgaard and Kiehn 1985; Schwindt and Crill 1977; Sigvardt et al. 1985; Lee and Heckman 1998a). Physiologically, bistability arises due to plateau potentials that develop and persist on a slower timescale (order of seconds to minutes) relative to the millisecond timescale action potential events. In most adult vertebrates, plateau potentials are generated by noninactivating “persistent inward currents” (Lee and Heckman 1998b) predominantly composed of low-voltage-activated L-type calcium and to a lesser extent by persistent sodium currents (Lee and Heckman 1996; Li and Bennett 2003). It is generally accepted that such currents are of dendritic origin (Carlin et al. 2000). When activated, they produce a persistent plateau in the somatic membrane voltage that can be sufficient to sustain action potentials even after the removal of plateau producing depolarizing input – also known as “self-sustained firing” (see Fig. 1). Additionally, activation of plateau potentials can induce higher-frequency

Conductance-Based Models of Nonlinear Dynamics in Vertebrate Motoneurons, Fig. 1 Bistable membrane behavior in vertebrate motoneurons. *Left:* Somatic current injection (I_{soma}) marked by red asterisk induced somatic spikes (dark green) that in turn also activates dendritic plateau (dendrite switches from OFF to ON state). This dendritic plateau persists even after the somatic current returns to its initial level (demarcated by vertical dotted line) at which the soma was silent. This sustained plateau now drives somatic spikes resulting in self-

sustained firing (light green). Black circles indicate zero I_{soma} . *Right:* Figure shows the two levels of I_{soma} , low current (black triangle) that initially induces a low-frequency firing in the soma (orange) but does not activate the dendrite followed by a brief high I_{soma} (red asterisk) that turns on the plateau. Subsequent return of I_{soma} to its initial value (black triangle) results in a higher-frequency firing (yellow) due to the additional persistent depolarization by the dendritic plateau

firing for the same depolarizing current injection that produced a low-frequency firing before plateau activation (see Fig. 1).

generate physiologically realistic membrane voltage responses and firing behavior in the specific motoneurons being modeled (e.g., Booth et al. 1997; Kurian et al. 2011; Venugopal et al. 2011, 2012).

Models of Motoneuron Bistability

Models of motoneuron bistability have faithfully captured the nonlinear dynamics arising at the soma in experimental settings.

There are two basic features of these models that are critical for reproducing the experimentally observed bistable membrane properties in motoneurons. They include (1) the presence of at least two *weak/moderately* coupled compartments and (2) sufficiently disparate membrane properties between the compartments (e.g., dendritic localization of persistent inward currents). A classic two-compartment conductance-based model that first explored the phenomenology of vertebrate motoneuron bistability is the Booth-Rinzel model (Booth and Rinzel 1995) that included dimensionless equations. Similar two-compartment models incorporated more realistic biophysically based ionic conductances to

A Minimal Motoneuron Model for Understanding Bistable Membrane Behavior

Figure 2 shows the model schematic of a minimal two-compartment vertebrate motoneuron. The equations guiding this minimal model are given below:

Shown here are minimal set of ionic currents that include fast sodium (I_{Na}) and delayed rectifier potassium (I_{Kdr}) in the soma for action potential generation, a voltage-dependent persistent inward current in the dendrite (I_{PIC}) that mediates dendritic plateau, a leak current (I_{leak}) in both the compartments to maintain the resting potential, a coupling current (I_{coup}) that arises due to the electrotonic coupling of the compartments whose magnitude depends on the coupling conductance

Conductance-Based Models of Nonlinear Dynamics in Vertebrate Motoneurons, Fig. 2 Minimal motoneuron model of bistability. *Left:* A schematic showing the morphological and electrophysiological components of the model consisting of two electrotonically coupled

Somatic compartment:

$$\frac{dV_S}{dt} = -I_{Na} - I_{Kdr} - I_{leak} + I_{coup} + I_{soma}$$

$$\frac{dw_S}{dt} = \phi_S \frac{w_S^\infty - w_S}{\tau_w}$$

Dendritic compartment:

$$\frac{dV_D}{dt} = -I_{CaP} - I_{leak} + I_{coup}$$

$$\frac{dm_{CaP}}{dt} = \frac{\varepsilon_D (m_{CaP}^\infty - m_{CaP})}{\tau_{CaP}}$$

compartments, namely, soma and dendrite. *Arrows* show the directions of inward and outward currents (see text for description of currents). *Right:* Equations guiding the membrane voltage dynamics in somatic and dendritic compartments

(g_c), and the proportion of area (p) suggested to be occupied by the soma. The term I_{soma} refers to somatic current injection. The somatic and dendritic voltages are given by V_S and V_D , respectively. For a detailed description of the model, see (Booth and Rinzel 1995). Note that these form a general set of equations and conductances guiding the somatic and dendritic compartments and one can easily incorporate additional terms for ionic currents as well as increase the morphological complexity as relevant. Alternatively, such minimal models could guide the development of artificial motoneurons that may act as bistable switches in neuromorphic circuits.

Hysteresis in the Frequency-Current Relationship and Mechanism Underlying Bistability

Motoneuron bistability described above can give rise to a counterclockwise hysteresis in the injected current firing frequency relationship (f-I) (see Fig. 3, *top*) although existence of f-I hysteresis itself is not sufficient for bistability.

Of importance in the f-I curve shown are the three ranges of firing frequencies, (1) primary, (2) secondary, and (3) tertiary ranges (see Kernell 1965; Schwindt 1973 for the first descriptions), that together lead to a counterclockwise hysteresis

to the f-I relationship. Use of geometric dynamical systems methods has provided insight into the mechanism of bistability and the emergence of the three frequency ranges. Figure 3 (*bottom*) shows a typical bifurcation structure of the dendritic voltage V_D with I_{soma} as the parameter. In the class of two-compartment models described above, this corresponds to an S-shaped curve for a range of coupling conductances characterized as weak-moderate (e.g., see Booth and Rinzel 1995; Kurian et al. 2011). The lower branch (dendrite OFF) consists of stable fixed points (non-spiking steady states/resting) and a stable oscillatory regime. The upper branch (dendrite ON) also consists of stable fixed points (non-spiking plateau state) and a stable oscillatory regime. The height and width of the S shape as well as that of the regimes described are dependent on the properties of the ionic conductances considered (e.g., note differences among the various models Booth et al. 1997; Kurian et al. 2011; Venugopal et al. 2011). Superimposing the dendritic voltage changes during a somatic triangular ramp current injection in the model clarifies that (1) the primary firing frequencies correspond to the oscillatory frequencies emerging at the lower branch, (2) tertiary frequencies correspond to the oscillatory frequencies emerging at the upper branch, and (3) secondary frequencies would arise during plateau development and are transitory see (Venugopal et al.

Conductance-Based Models of Nonlinear Dynamics in Vertebrate Motoneurons, Fig. 3 Bifurcation analyses of emergence of f-I hysteresis and bistability. *Top:* Schematic of f-I relationship in response to a somatic triangular ramp current injection (I_{soma} trace not shown, but see *curved arrow* showing direction of I_{soma} changes). Spiking begins in the soma in the primary frequency range (*blue*) and continues into a steeper secondary range (*red*) as I_{soma} ramps up. On the descending I_{soma} ramp, tertiary frequencies (*green*) give rise to a counterclockwise hysteresis in the f-I relationship. *Bottom:* Bifurcation curve showing the various steady-state regimes. The *bold lines* in the steady-state *S-shaped curve* indicate stable fixed points and *broken lines* indicate unstable fixed points. *Blue dotted*

lines demarcate the amplitude of dendritic oscillations due to soma firing in the primary range (only stable oscillations are shown here). *Red dotted lines* demarcate the amplitude of dendritic oscillations due to soma firing in the tertiary range. Note that there are no stable steady-state oscillations for the secondary range in this diagram suggesting that these frequencies are transitory. Bistability-1 (region between *left orange* and *magenta vertical lines*) marks the region where tertiary firing and (stable) non-spiking state can coexist underlying self-sustained firing described earlier. Bistability-2 (region between *magenta* and *right orange vertical lines*) marks the region where primary and tertiary firing can coexist as described earlier in Fig. 1 (*right*)

2011). The same is illustrated using the steady-state bifurcation diagram (see Fig. 3) of dendritic voltage in response to I_{soma} clarifying that only 1° and 3° frequencies are stable oscillatory states, while the secondary range arising during plateau development is not evident as a stable steady state. This critical insight suggests the possible window of modulation of the plateau by synaptic inputs in turn regulating motoneuron firing frequencies and muscle output.

In summary, conductance-based mathematical models of vertebrate motoneurons have been

useful platforms to examine nonlinear dynamics in these neurons and have provided important insights into the basis of experimentally observed membrane properties in this important class of cells in the nervous system.

Connectionist Models of CPG Networks

Sharmila Venugopal

Department of Integrative Biology and Physiology, University of California, Los Angeles, Los Angeles, CA, USA

Detailed Description

Central Pattern Generators (CPGs) are neural networks that can produce coordinated patterns of rhythmic activity to orchestrate repetitive behaviors such as feeding, locomotion, and respiration. CPGs are known to be composed of phylogenetically conserved connectional units that are typically organized into chains to enable coordinated activation of the effector organs (muscles). Through integration of experimental and computational approaches at the cellular and network levels, essential connectional elements of CPGs have been revealed (Grillner 2006).

Network Topology At the connectional level, a CPG network consists of “unit CPGs” representing the nodes of the network, and the reciprocal connections between unit CPGs correspond to the branches of the network. Physiologically, a unit CPG represents a group of neurons that can generate a recurrent burst of activity (Grillner 2006).

Simple inputs such as tonic excitation can produce rhythmic outputs in these networks. Increasing the stimulus strength typically increases the frequency of the network rhythm. Two unit CPGs are reciprocally coupled by mutual inhibition to generate alternating activity patterns (Fig. 1a) or by mutual excitation to generate synchronized bursts (Fig. 1b). Many unit CPGs connected in a chain with mutual excitation can generate a progressive phase lag in the bursts of activity along the CPG chain (Fig. 1c). It is generally accepted that rhythmogenesis is intrinsic to the neurons forming the unit CPG.

Connectionist Models of CPG Networks, Fig. 1 Schematic of typical connective elements of a CPG network. Unit CPGs with (a) reciprocal inhibitory (blue) and (b) reciprocal excitatory (red) connections are shown. (c) A chain of unit CPGs with reciprocal excitatory connections. The thick black lines in a, b, and c represent

the duration of CPG drive signal, and blue and red waveforms represent out-of-phase (a) and in-phase (b) activity. In (c), the *thin black lines* indicate reduced drive to the corresponding unit CPGs such that the top unit leads and subsequent phase lags are produced in the onset of activity as we go down the chain

However, connectionist models of CPG networks have unequivocally demonstrated that rhythmic patterns can be a resultant of a topology of connections among unit CPGs (Buchanan 1992). Hence, based on the nature of connections between unit CPGs, a CPG network can generate and shape patterns of activity.

Reconfiguration of CPGs Central pattern generators can reconfigure to switch from one activity pattern to another to produce multiple forms of the same behavior (e.g., walking, running, and galloping as different forms of locomotion) or functionally distinct behaviors (e.g., normal breathing versus gasping). Mathematical and simulation models suggest that the mechanisms underlying the reconfiguration of CPGs may include (1) altered strength and duration of the excitatory drive to the CPG network (e.g., Jung et al. 1996), (2) altered strength and duration of the mutual connections between unit CPGs (e.g., Venugopal et al. 2007), and (3) recruitment and

de-recruitment of unit CPGs (e.g., Nasse et al. 2008). Such reconfiguration of a given CPG network architecture can confer multifunctionality.

Unit CPG Models Biophysical models of unit CPGs are typically based on conductance-based Hodgkin-Huxley formalism to model the constituent neurons with one or more compartments (e.g., see review Grillner et al. 2005). In models that exclusively focused on network properties, nonlinear oscillators have been widely used to represent unit CPGs (e.g., see review Ijspeert 2008). It appears that the network activity pattern of interest can be produced irrespective of the type of the oscillator model (e.g., Collins and Richmond 1994). This provides various options for choosing a suitable oscillator to represent the unit CPGs/nodes, particularly when mathematical analyses are adopted for gaining mechanistic insight into network behavior. Moreover, simple oscillator models are suitable choices for prosthetic and/or robotic applications.

Parameter Tuning in CPG Networks Identification of intrinsic and synaptic properties/parameters of CPG networks that produce the shape and the nuances of activity patterns is at the core of neurobiological investigation of CPGs. Biophysical models of CPGs often adopt brute force methods for parameter tuning within physiological ranges (Prinz et al. 2004). Alternatively, artificial CPG networks for engineering applications have utilized artificial neural network learning algorithms to estimate network parameters (e.g., Ijspeert 2008).

Definition

Connectivity analysis focuses on the neural network basis of the brain and characterizes topological and other aspects of brain network organization that appear relevant for understanding normal and pathological brain function.

Detailed Description

Brains as Networks

The network perspective of the brain integrates aspects of local versus distributed brain function, combining *segregation* and *integration* of components. Brain connectivity can be intuitively represented as *graphs*, where *nodes* represent neural elements, ranging in scale from individual cells to large-scale neural populations (e.g., cortical areas) and *links*, representing structural or functional associations between the nodes. This simplifying approach is based on the assumption that neural elements are intrinsically homogeneous and that their interactions are determined by anatomical connections.

Several types of connectivity can be distinguished (Friston 2004):

- *Structural*: the physical coupling of neural elements by neuronal connections.
- *Functional*: statistical dependencies in the dynamics of neural elements.
- *Effective*: the dynamic or functional impact exerted by one neural element on another.

Node elements can be defined by morphological, anatomical, or functional criteria, for instance, anatomical landmarks, cytoarchitectonic characterization, or functional activation patterns, respectively. Moreover, nodes can also be parcellated by their characteristic connectional fingerprint. Importantly, the way in which node parcels are defined also affects the density and topological features of the studied networks (de Reus and van den Heuvel 2013).

Structural connectivity is mostly derived from invasive approaches in animal models (histochemical or viral pathway tracing, polarized light imaging (PLI) of fibers, or optogenetic manipulation of projection neurons) and noninvasive investigations of the human brain (indirect characterization of tracts by diffusion-weighted magnetic resonance imaging, dwMRI). Depending on the studied type of connectivity and empirical constraints, one can consider *directed* versus *undirected* connectivity. For instance, human brain structural connectivity derived from diffusion-based MR imaging is typically undirected, whereas histochemical tracing in animal models allows identifying the origins and terminations of projections. Another distinction can be made of *binary* versus *weighted* networks. The former contain information on the existence or absence of links, while the latter also include information on the strength of edges (Rubinov and Sporns 2011).

Network organization matters functionally, in the ultimate sense that there are systematic connectivity differences between the brains of healthy subjects and patient groups (Bullmore and Sporns 2012). Central aspects of connectivity organization are network *geometry* (i.e., the spatial embedding of networks) versus *topology* (nonspatial features of connectional organization) (Bullmore and Sporns 2009; Sporns et al. 2004).

Topological Features of Brain Connectivity

Topology describes the connectional organization of a brain network, independent of its spatial arrangement. Topological features can be loosely ordered from more local to more global aspects. Some features are summarized in the following list. They are described in more detail in the recent research literature (Kaiser 2011; Rubinov and Sporns 2010; Sporns 2011; Stam and Reijneveld 2007).

Node Features

- *Degree*: the total number of incoming (afferent, in-degree) and outgoing (efferent, out-degree) links of a node; the *degree distribution* of nodes is a characteristic indicator of different classes of networks.
- *Strength*: the graded degree of weighted connections.
- Further node indices can be defined, such as the proportion between incoming and outgoing projections (Kötter and Stephan 2003).

Circuit Features

- *Motifs* or circuits are subnetworks consisting of relatively few nodes or links; motif spectra appear to be characteristic for different classes of biological networks (Milo et al. 2004).
- *Paths* are ordered sequences of unique edges, while *walks* are sequences of nonunique edges; *cycles* are paths leading back to the same node; the length of *shortest paths* (or its inverse, *local efficiency*) is frequently taken as an indicator for the potential length of minimal interaction distances in a network.
- Local *clustering* (cliquishness): the proportion of existing connections among the neighbors of a node.

Global Network Features

- Overall *density* of wiring: the total number of existing links in a network, out of all possible ones.

- The average shortest path (or its inverse, global efficiency).
- Network *diameter*: the longest shortest path.
- Further features can be considered at the scale of the whole network including *assortivity*: the similarity of the degree of linked nodes, as well as averages of node or circuit-based indices, such as clustering.
- Existence, number, and size of *modules*, which are formed by nodes that are more frequently or densely linked with each other than with the rest of the network.
- *Hubs*, which can be identified by a variety of measures, such as the node degree, node *centrality* (in terms of representation in the network paths), or vulnerability, and which may be *global* or *provincial* hubs depending on their placement in the network.
- *Hierarchy*: the encapsulation of features within features (e.g., modules of modules in *hierarchical modular networks*); however, hierarchy can also be defined in various other ways, e.g., by the local versus global access of nodes in a network (Müller-Linow et al. 2008).

It is important to note that network features at the same or different scales may be interrelated. For instance, dense networks may result in densely wired motifs.

Benchmark Networks

Benchmark networks can be based on the degree distribution of nodes. In so-called *Erdős-Rényi* or *random* networks, the probability, $p(k)$, of nodes possessing an edge degree k follows a Gaussian distribution, whereas the degree of nodes is constant in *regular* or *lattice* networks. *Small-world* networks can be seen as regular networks with a fraction of random links; they possess clustering comparable to regular networks and average shortest paths similar to random graphs. In *scale-free* networks, $p(k)$ follows a power law; thus, these networks lack a characteristic scale. Benchmark networks can also be constructed for a variety of other topological measures, for

instance, yielding *random modular* graphs or different types of hierarchical networks (Kaiser 2011).

There are also several established datasets for biological *connectomes*, in particular for cortico-cortical connections in the cat (Scannell et al. 1999), the rhesus macaque (Felleman and Van Essen 1991; Markov et al. 2014) as well as mesoscopic connections of the human brain based on diffusion MRI (Hagmann et al. 2008). Moreover, connectomes or partial connectomes at the cellular level exist for *Caenorhabditis elegans* (Varshney et al. 2011), drosophila (Chiang et al. 2011), and zebra fish (Stobb et al. 2012). From these datasets, further benchmarks can be derived, such as randomized versions preserving features, for example, the degree distribution, or pairwise degree distribution.

Geometry of Brain Connectivity

Brain networks are spatially embedded. The distance among neural elements may influence physiological and functional parameters through delays and metabolic costs and place constraints on the existence and strength of links. Consequently, it is a popular idea that brain networks should have compact wiring. However, other structural, functional, metabolic, or evolutionary constraints might also be important and there may be trade-offs between various, partly antagonistic constraints on brain connectivity (Chen et al. 2013; Kaiser and Hilgetag 2006).

Pathological Brain Connectivity

Aberrations in brain function arise from perturbations of local neural structures and mechanisms (i.e., node perturbations) as well as perturbed interactions between remote regions. The latter pathologies can be considered as *disconnexion* (disrupted connectivity) (Geschwind 1965) or *dysconnection* (maladjusted connectivity) syndromes (Stephan et al. 2009). Systematic differences in structural and functional connectivity

have been found between healthy controls and different patient samples, for example, with *autism* or *schizophrenia* spectrum disorders (Bullmore and Sporns 2012).

A well-studied example of the network perspective is *Alzheimer's disease* (AD), in which highly connected hub nodes of human functional brain connectivity show high metabolic activity as well as an affinity for the accumulation of *beta-amyloid* protein, thus, becoming the origin for the propagation of AD (Buckner et al. 2009).

Generally, however, it is currently unclear which network features contribute causally to different aspects of network dynamics or function.

Definition

The *Drosophila* connectome is a comprehensive description of all the connections between subunits comprising the central nervous system (CNS) of the fruit fly, *Drosophila melanogaster*.

The CNS of *Drosophila* consists of the brain and ventral ganglion. It has a volume of $\sim 0.07 \text{ mm}^3$ (see Rein et al. 2002, Table 1). To compare, this is similar to the volume of a single cortical column in mouse barrel cortex ($\sim 0.09 \text{ mm}^3$) (Lefort et al. 2009; Hooks et al. 2011). The *Drosophila* brain can be subdivided into smaller neuropil compartments (Fig. 1), identified through anatomical boundaries (Ito et al. 2014), as well as the overlapping arborizations of the neurons constituting each neuropil compartment (Chiang et al. 2011; Jenett et al. 2012). In total, across these compartments, the *Drosophila* brain is thought to contain $\sim 90,000$ cells, of which $\sim 90\%$ are neurons. These neurons can be classified into

Connectome, *Drosophila*, Fig. 1 *Drosophila* brain with anatomically identified neuropil compartments individually colored (www.flybrain.org (AB00122)). Scale bar: 100 μm

discrete cell types, with stereotypical shapes and synaptic connections, using both human observation and genetic reporter lines that label individual types.

A *Drosophila* connectome, within the brain, can be constructed at different levels of resolution. At low resolution, a connectome can be said to comprise neuropil compartments, with connections between them defined by neural pathways, as identified by light microscopy. In contrast, at high resolution, a connectome comprises individual neurons and all the chemical synapses between them. The components of such a cellular connectome are identified through electron microscopy (EM).

As of 2013, neuropil-level connectomes have been constructed for the entire *Drosophila* brain (Chiang et al. 2011), but only partial cellular connectomes have been reported. In particular, cellular connectomes have been reported for a cartridge of the lamina (Meinertzhagen and O'Neil 1991; Rivera-Alba et al. 2011) and a column of the medulla (Takemura et al. 2013), the first and second neuropil compartments, respectively, within the fly optic lobe (transmitting visual information). Despite their incomplete nature, these partial connectomes have already provided valuable insights into the computational functions of neuronal circuits.

Existing Neuropil-Level Connectomes

Large-scale, compartmental maps of the *Drosophila* brain have been obtained through the use of genetic reporters imaged by light microscopy (Chiang et al.

Connectome, *Drosophila*, Fig. 2 Reconstructing a cellular connectome using ssTEM. (a) TEM image of part of a 40-nm-thick section, 1 of 2769 sections imaged to reconstruct the medulla connectome. (b) Applying computational segmentation algorithms, followed by human proofreading on the TEM images, is necessary to isolate

neuronal cross sections (neurite profiles in single colors). (c) Profiles in consecutive sections (left) are linked to construct 3D neurites (right). (d) A subset of reconstructed neurons, embedded within the imaged neuropil. (e) Rendering of neurites belonging to 379 reconstructed neurons. Scale bar: 500 nm (a, b)

2011). Each reporter line fluorescently labels a sparse subset of neurons (Jenett et al. 2012; Ito et al. 2013). Aligning images from multiple lines to a standard *Drosophila* brain, the overlapping arbors of locally arborizing neurons are used to define individual compartments: local processing units (LPUs) (Chiang et al. 2011). The connections between these LPUs are found by identifying neurons projecting between them. In total, the resulting connectome contains 58 tracts between the 41 identified LPUs, a sparse subset (<10%) of the 820 numerically possible LPU-LPU connections.

Cellular Connectomes and EM

A neuropil-level connectome, generated from light microscopy, has insufficient resolution to

identify synapses and hence cannot detail the true connections between neurons. The large-scale, dense identification of all synapses within a region of neuropil requires higher resolution EM-based methods, typically serial-section transmission EM (ssTEM) (Fig. 2). However, these techniques are labor intensive and time-consuming. Therefore, only a few partial cellular connectomes have been reconstructed, specifically for two *Drosophila* optic lobe neuropils.

Optic Lobe Cellular Connectomes

The optic lobe of flies has been the subject of experimental interest for over 50 years, driven by the advanced visual behaviors of flies (Heisenberg

and Wolf 1984). Despite the large size of the optic lobe, encompassing almost 50% of the total CNS volume (Rein et al. 2002), the modular structure of its underlying neuropil compartments, corresponding to the ommatidia array of the compound eye, is highly amenable to connectomics.

Within the optic lobes, synapses are divergent polyads (Fig. 3), i.e., each presynaptic specialization (or “T-bar”) is typically associated with four to six postsynaptic dendrites. This divergence is expected to generalize to non-optic lobe neuropils, though the number of postsynaptic targets may vary across neuropils.

Lamina

The lamina receives most of its input directly from photoreceptors in the retina. It is thought to be mostly responsible for encoding contrast and for light adaptation. A cellular connectome of the repeating unit of the lamina, the lamina cartridge, has been reconstructed twice, in two different wild-type strains (Meinertzhagen and O’Neil 1991; Rivera-Alba et al. 2011). Both reconstructions are similar, with most differences apparently introduced by improvements in reconstruction quality and by differences in the interpretation of some

postsynaptic elements. The consensus lamina connectome contains the terminals of six photoreceptors, along with 12 types of neurons (Rivera-Alba et al. 2011; Tuthill et al. 2013). In total, each cartridge contains ~480 presynaptic sites, contacting ~1250 postsynaptic sites.

Medulla

Directly downstream of the lamina, the medulla is the single largest neuropil of the fly’s brain and receives visual input both through the lamina and directly from a subset of photoreceptors. It is thought to be responsible for (1) the computation of local visual motion, by the comparison of inputs from different points in space, and (2) color vision, utilizing the direct inputs from spectrally tuned photoreceptors.

A connectome of the repeating unit within the medulla, the column, was reconstructed recently (Takemura et al. 2013) (Fig. 4). It reports the connections between 56 identified cell types, of which 27 are modular (contained in every column). As in the lamina, each presynaptic site contacts multiple postsynaptic elements (~3.8 on average). Within a column, the modular cell types are connected by ~2500 synaptic contacts. However, this is only a subset of the ~5800 synaptic contacts that these same modular cell types make in total, showing clearly that there are far more cross-column connections in the medulla than in the lamina (Rivera-Alba et al. 2011).

Characteristics of the *Drosophila* Connectome

Presynaptic terminals within the existing connectome reconstructions are typically of uniform size, and the number of synaptic contacts between different neuron pairs ranges over more than two orders of magnitude (1–150). Hence the synaptic weight for any pair is thought to be well approximated by the number of synapses in parallel. However, it is not known if it will be possible to generalize this quantitative assumption to the rest of the *Drosophila* connectome.

Connectome, *Drosophila*, Fig. 3 Divergent polyadic synapse. The presynaptic process, identified with a T-bar (red arrow), is associated with four postsynaptic dendrites (blue arrowheads). These postsynaptic processes can be distinguished from adjacent, unconnected processes (e.g., green circle) by their postsynaptic densities. Scale bar: 250 nm

Connectome, *Drosophila*, Fig. 4 3D graph of a connectome module: the connections between neurons found in every medulla column. The dominant direction of signal flow is oriented into the page. Cell types with stronger connections are positioned closer to each other. The colors identify three spatially segregated groups of neurons and, hence, three pathways of information transmission within the medulla

Synapse numbers for identified neurons are consistent across neurons of the same type in the lamina and medulla. However, as has been seen in both the antennal lobe (Chou et al. 2010) and the mushroom body (Murthy et al. 2008; Caron et al. 2013), this may not generalize to other parts of the brain. In general, learning associated or other forms of plasticity may decrease the stereotypy in the numbers of synaptic contacts, thereby increasing the difficulty of obtaining a single, defined connectome.

The Utility of Connectome Information: Functional Studies

One rationale for compiling a cellular connectome is to gain insight into the neuronal implementations

of behavior. The existing optic lobe connectomes have already demonstrated such utility. They have been used to direct the attention of genetic experiments toward a specific neuron(s) (Gao et al. 2008) and to provide the neuronal circuit substrates for computational analyses (Takemura et al. 2013). For example, the comprehensive nature of the cellular connectome reconstruction in the medulla allowed the identification of candidate neurons comprising a circuit computing local motion, a computation that had been intensely studied for more than 50 years (Borst et al. 2010), yet with limited prior insight.

In Progress

As of 2013, ongoing *Drosophila* reconstruction projects include the larval CNS connectome (Cardona et al.) and the connectome for seven medulla columns, utilizing a new imaging technique: focused ion beam milling scanning EM (FIB-SEM). FIB allows improved z-axis resolution, enabling more complete tracing of neurites thinner than the section thickness. This results in a more complete connectome, given that only 50% of the postsynaptic sites could be traced to an identified neuron in the ssTEM dataset. Further, by including multiple columns, the resulting connectome should also allow an estimate of the variation between columns, as well as the exploration of color vision circuits (Franceschini et al. 1981).

The Future

We are obviously at the early stages of assembling the components of the *Drosophila* cellular connectome. However, from the current rapid pace of improvements in sample preparation, imaging, and software tools for reconstruction, it seems possible that the cellular connectome will become available for the entire fly's CNS. This will require improvements in staining and sample preparation, increased reliability and speed of imaging, and improved automated image analysis algorithms. Additionally, information on the

polarity of synaptic transmission, and the presence of electrical synapses, neither visible from EM, must be incorporated from other techniques (Meinertzhagen and Lee 2011). However, even prior to the completion of the entire connectome, the demonstrated utility of the existing pieces of the *Drosophila* connectome suggests that each additional reconstruction should provide valuable biological insight.

Engineering, Texas A&M University, College
Station, TX, USA

Definition

Connectome is the full connection matrix (or the full wiring diagram) of all neurons in the brain (Sporns et al. 2005). Current efforts in connectomics (study of the connectome) can be grouped along two axes, one based on scale (macro [or regional] vs. micro [or cellular] connectome) and the other based on research focus (data acquisition technology vs. theoretical frameworks and analysis). The end goal of connectomics is to understand how the brain works based on its intricate circuitry, i.e., to go from complete structure to detailed function. See Seung (2012) and Sporns (2011, 2012) for a general overview of connectomics.

Detailed Description

The main underlying assumption in connectomics is that the brain's connective architecture determines in large part its function (Sporns 2012; Seung 2012). This assumption can be put in an evolutionary

context, as noted by Swanson (2003): Evolution from simple neuronal networks in primitive animals to complex brains of animals like humans happened mostly in its architecture, not in its components.

Current Status of Connectomics

Connectomics aims to obtain the connectome from the whole brain and analyze it in full detail at subcellular resolution. However, because of technological limitations, current efforts are focused on either small volumes (on the order of 100 μm) of nm resolution samples or large volumes (whole brain) at hundreds of μm resolution. Connectomes at these two different scales are called micro (or cellular) connectome and macro (or regional) connectome, respectively (see, e.g., DeFelipe 2010).

Currently, the only full connectome that is available is that of the nematode *Caenorhabditis elegans*. All 302 neurons, their connections, and other somatic cells have been mapped out fully (White et al. 1986). Various connectivity analysis (e.g., Watts and Strogatz 1998; Kaiser and Hilgetag 2006; Sohn et al. 2011) and open-source simulation efforts (OpenWorm, <http://openworm.org>) are based on the *C. elegans* connectome data.

The *Drosophila* connectome has also been extensively mapped (379 neurons and 8637 chemical synapses) in the medulla of the optic lobe (Takemura et al. 2013). However, due to the complexity of the *Drosophila* brain compared to that of the *C. elegans* ($\sim 90,000$ cells in its brain, of which $\sim 90\%$ are neurons), the full connectome has not been mapped. See ► “Connectome, *Drosophila*” for details.

Cellular-level connectome (nm resolution) of larger animals seems to be beyond the horizon at the moment, although technologies for obtaining such data are actively being developed. For an overview of such methods, see ► “Physical Sectioning Microscopy,” especially those employing electron microscopy, e.g., serial block-face EM (Denk and Horstmann 2004) and automated tape-collecting ultramicrotome (Hayworth et al. 2006). These techniques have been used to map small volumes of neural circuitry ($\sim 100^3 \mu\text{m}^3$) at

nm resolution (on the order of 10 nm), for example, the mouse retina (Helmstaedter et al. 2013) or the rabbit retina (Anderson et al. 2011). At a similar scale, Bock et al. (2011) combined functional imaging (two-photon calcium imaging) and serial transmission EM to image 450 μm wide and 350 μm deep volume from the mouse visual cortex (this data set is available through the Open Connectome Project <http://openconnectomeproject.org>). In a similar vein, Mishchenko et al. (2010) studied the ultrastructure of rat hippocampal neuropil from serial sectioning transmission EM images (45–50 nm thick sections, 2.2 nm in-plane resolution).

At the μm scale, light microscopy techniques are being developed for connectomics, with the aim of obtaining local circuits based on histological stains (e.g., knife-edge scanning microscopy and related techniques; Mayerich et al. 2008; Chung et al. 2011; Li et al. 2010a; Fig. 1) and long-range projections based on tracer injections (Hintiryan et al. 2012; Mitra 2012). The typical volume that can be imaged with these methods is $\sim 1 \text{ cm}^3$ at the resolution of $\sim 1 \mu\text{m}$. See ► “Physical Sectioning Microscopy” and Kleinfeld et al. (2011) for related approaches such as array tomography, serial two-photon tomography, and all-optical histology. Optical sectioning techniques such as scanned light-sheet microscopy (Keller et al. 2008) are also promising, especially when combined with tissue-clearing methods like CLARITY (Chung and Diesseroth 2013). Fluorescence probes are routinely used to label distinct neuronal types or molecular signatures such as presynaptic vs. postsynaptic densities for the detection of synaptic connections. Most of the above techniques have been applied to mouse brain imaging (see ► “Connectome, Mouse” for publicly available data). However, the available data are only partial and in many cases geometric reconstructions are not available; thus analysis based on the data is scarce. Some reconstructions are available for small volumes of the mouse neuromuscular junction connectome ($\sim 100^3 \mu\text{m}^3$ at $\sim 0.2 \mu\text{m}$ resolution), where the brainbow technique was used (Srinivasan et al. 2010).

At the highest spatial scale, neuroimaging methods are used to map the macro (or regional)

Connectome, General, Fig. 1 Circuits in the mouse hippocampus. Screenshot from the Knife-Edge Scanning Microscope. Brain Atlas <http://kesm.org>, inverted and contrast enhanced (Chung et al. 2011; Mayerich et al. 2008).

The Golgi data set shown is an overlay of thirty 1 μm -thick sections at an interval of 2 μm , representing a tissue thickness of 60 μm . The voxel resolution is 0.7 $\mu\text{m} \times 0.6 \mu\text{m} \times 1.0 \mu\text{m}$

connectome. These techniques are mostly based on diffusion magnetic resonance imaging (dMRI; Park et al. 2008; Hagmann et al. 2007, 2008; Johansen-Berg and Rushworth 2009), with the exception of 3D-polarized light imaging (3D-PLI; Axer et al. 2011). Major white matter tracts can be imaged using these approaches. The volume covered by these techniques is often as large as the human brain (on the order of 10^3 cm^3), but the imaging resolution is low, about 2 mm for dMRI and about 30 μm for 3D-PLI. Serial sectioning has been employed on whole human brain at 20 μm sectioning thickness with in-plane resolution of 10 $\mu\text{m} \times 10 \mu\text{m}$, but the histological stain used only labeled cell bodies; thus, connectivity could not be established (Amunts et al. 2013). Although the resolution is low, data from this scale has been analyzed most intensely compared

to connectomes at different spatial scales. It is also notable that connectivity matrices derived from tracer injection methods are available at this scale, such as that of the macaque (► “[Collations of Connectivity Data on the Macaque Brain \(CoCoMac\)](#)”; Felleman and Van Essen 1991) and the cat (de Reus and van den Heuvel 2013). Simulation of an entire thalamocortical network of the human brain based on dMRI connectivity data (Izhikevich and Edelman 2008) and extensive connectivity analysis exists at this scale (see Chap. 5, The Connectome at the Macroscale, in Sporns 2012, and ► “[Human Connectome Project](#)”).

Across the multiple scales, connectomics research is already producing deep insights into the organization and function of the brain, e.g., (1) discovery of new cell types based on

morphology and connectivity (Helmstaedter et al. 2013), (2) organizing principles such as the “rich club” (nodes with high connectivity are more heavily connected among themselves; van den Heuvel and Sporns 2011; de Reus and van den Heuvel 2013), (3) emergence of activation patterns and sensitivity of the pattern to small local changes (Izhikevich and Edelman 2008), (4) wiring optimization principles (see ► “[Wiring Principles, Optimization](#)”), (5) changes in the connectome due to neurodegeneration (Zhou et al. 2012), and (6) identification of functionally distinct neuronal populations based on connectivity (Sohn et al. 2011).

From Raw Data to Geometry, Connectivity, and Databases

The imaging data obtained using the techniques outlined above are prone to noise and distortions; thus, noise and artifact removal using image processing algorithms is a necessary first step. Next, denoised images need to be registered so that an aligned 3D volume can be constructed (note that some methods do not require such a registration step). The last step of assembling the connectome is to reconstruct the geometry of all neurons and their connections from the image volume (see ► “[Reconstruction, Techniques and Validation](#),” and ► “[Reconstruction, Electron Microscopy](#)”). This is no trivial task, and researchers are exploring (1) manual (e.g., Fiala 2005), (2) automated (Jain et al. 2010; Bebis et al. 2010; Edwards et al. 2013), (3) crowd-sourcing-based (e.g., the EyeWire Project <http://eyewire.org>; Helmstaedter et al. 2013), and (4) a hybrid of automated and manual methods (Chklovskii et al. 2010; Mishchenko et al. 2010).

Once the full geometric description of all neurons is known, the connectivity needs to be established. In electron microscopy (EM) data, synapses can be inferred based on synaptic densities and synaptic vesicles and by locating gap junctions (Xu et al. 2013). Several manual and automated methods have been developed for this, e.g., Chklovskii et al. (2010), Xu et al. (2013), and Kreshuk et al. (2011). Aside from

EM data, exact connectivity cannot be established, unless molecular markers such as synaptophysin-GFP are used to explicitly mark the synapses (Li et al. 2010b). For example, data based on light microscopy typically show only a fraction (~1% for Golgi) of the entire population of neurons. In this case, we need to estimate connectivity. Methods like those proposed by Kalisman et al. (2003) can be used. One way to test the validity of such an approximation is as follows. First, conduct a systematic simulation study with a full synthetic circuit to establish a baseline. Next, drop a certain proportion of connections and observe the resulting change in behavior. The degree of redundancy in the connections (both for real and synthetic circuits) will play an important role here.

Informatics is also an important component in connectomics: how to represent and organize the image data and reconstructed geometry and connectivity. Standards for describing neuronal morphology such as ► “[NeuroML](#)” and classification and taxonomy schemes such as the Foundational Model of Connectivity (FMC) are being developed (Swanson and Bota 2010). Due to the massive amounts of data regardless of the imaging modality or scale, connectome data are generally made available through web-based multi-scale visualization environments (see Chung et al. 2011; Hintiryan et al. 2012; Mitra 2012; Mikula et al. 2007).

Analysis and Utilization of Connectome Data

Once the connectome is reconstructed and connectivity established, we need to analyze the data to gain new insights in brain structure and function.

Graph Theoretical Analysis With a full connectivity matrix, we can use standard graph theoretic measures such as in-degree, out-degree, clustering index, etc. (Barabasi 2002; Bullmore and Sporns 2009; Rubinov and Sporns 2010) and look for motifs (Watts and Strogatz 1998). See Kaiser (2011) for a tutorial.

Basic Circuit Analysis Stereotypical patterns of local circuits are a hallmark of brain architecture. These patterns are called basic circuits, and using these as a building block, large-scale circuit analysis can be conducted (Shepherd 2004). Connectome data can also enable systematic discovery of new basic circuit patterns.

Estimating Dynamic Parameters Certain dynamic parameters such as conduction delay can be estimated based on axon length and diameter. Simply calculating the delay distribution can already provide great insights into brain function. For example, Thiel et al. (2003) showed that the complexity of network dynamics critically depends on the delay distribution. (Also see Sporns et al. (2000) on the relationship between neuroanatomy and brain dynamics.) Compared to connectivity data, collections of delay data are relatively scarce, with few exceptions being the works by Lamme and Roelfsema (2000) and Nowak and Bullier (1997).

Bridging the Gap Between Structure and Function The connectome is fundamentally a static structure. How can physiological properties be inferred from just the structure? Toledo-Rodriguez et al. (2004) show a possibly powerful solution to this problem: use gene expression data (also see Markram 2006). They found that gene expression and electrophysiological properties are closely correlated. For approaches like this, existing gene expression data (e.g., the Allen Brain Atlas (Lein et al. 2007) and techniques that combine molecular and EM imaging serve as great resources (e.g., array tomography (Micheva and Smith 2007)) are great resources for this kind of approach. These approaches can also help determine the sign and strength of the synaptic connections (together with dynamic parameters discussed right above) which are important properties that influence function. For example, the function of a circuit can instantly become nontrivial to analyze when inhibition is involved, e.g., in various circuits that incorporate disinhibition.

Linking with Dynamic Data To obtain a more complete picture of the brain, eventually we will

need to combine structural and functional imaging of the brain. Near real-time calcium imaging of whole animals such as the zebra fish is already possible (Ahrens et al. 2013), and at the higher spatial scale, neuroimaging methods like magnetoencephalography (MEG) can be used (Larson-Prior et al. 2013). Functional and effective connectivity estimated using functional MRI (Friston 2011) could also be compared and contrasted with connectomics data. Some of the limitations of functional and effective connectivity estimation can be addressed through optogenetics (Lee et al. 2010).

Inter- and Intra-Specimen Variability Estimation Simply measuring the morphological variability among the same class of neurons can provide valuable insights into how redundant or specialized the functions are (Gerald Edelman, personal communication, 2009). Even when connectivity is not known, just examining the dendritic trees can give deep insights into neural computation (Mel 1994; Polsky et al. 2004).

Brute-Force Parameter Search and Simulation Of course a straightforward yet potentially valuable approach is to start with computational simulations based on detailed neuronal morphology (cf. the Blue Brain Project, Markram 2006). The reconstructed geometry can be used to construct multi-compartment models (see, e.g., Dayan and Abbott 2001). Appropriate parameters such as channel conductance, capacitance, etc. need to be figured out. Tools like NEURON, GENESIS, neuroConstruct, NeuGEN, Netmorph, etc. can be used for multi-compartment simulation and parameterized synthetic circuit generation/simulation/analysis (Hines and Carnevale 1997; Bower and Beeman 1998; Gleeson et al. 2007; Koene et al. 2009; Koene 2007; Ascoli et al. 2001; Eberhard et al. 2006). Connectomics data can help narrow down on the range of various parameters for these simulations (for parameter constraining procedures, see Druckmann et al. 2008).

Investigate the Effect of Link Fidelity A great matter of debate in connectomics is whether

individual connections matter (detailed EM info needed) or whether they can be averaged (diffusion MRI is enough). Some results suggest that dropping even a single spike in the initial condition can have a global effect on the entire cortex within 0.5 s (see Izhikevich and Edelman's (2008) large-scale simulation study of the thalamocortical system based on diffusion MRI data). However, considering that the brain in a normal operating environment is always anchored to the present input stimulus thus constantly resetting the initial condition, this may not be a serious issue. Issues like these can be studied based on circuit data estimated from the connectomics data sets.

Investigate Changes in the Connectome in Brain Disorders An important practical application of connectomics is to understand how brain disorders change or deteriorate the connectome. Preliminary work in this direction has already appeared: Zhou et al. (2012) showed how connectivity in health predicts regional vulnerability to disease (note: in this work, fMRI-based functional connectivity was studied, not structural connectivity). See ► [“Neuropathologies and Networks”](#) for details.

Novel Visualization Methods for Discovery The amount of connectome data that already exists surpasses our capability to analyze and understand them. In most cases, the connectome data are stored as numerical values, and humans are not good at dealing with such data directly. To enable discovery, novel real-time visualization methods may be necessary. Visualization should not be confined to rendering the geometry – various forms of filtering and statistical summary visualization based on local and global geometric properties (such as orientation, anisotropy, etc.) need to be developed. See Margulies et al. (2013) on visualizing dMRI human connectome data and Mayerich and Hart (2007) on visualizing serial EM data. Visual analytics for abstract information extracted from the connectome will also be necessary (see Meyer et al. 2010 for a discussion on visual analytics in general).

Challenges and Open Questions

A hotly debated open question in connectomics is regarding the scale: What level of detail is enough to completely replicate the architecture and function of the brain (Koene 2012)? This question arises partly due to the incompleteness of various data acquisition technology operating at scales ranging across several orders of magnitude, from EM to dMRI. There is no definite answer to this problem. In the next decade or so, for practical reasons, we will have to live with a patchwork of connectomics data from various scales, so we need to invent novel approaches to register and integrate connectome data from different imaging modalities at different scales.

One of the ultimate goals of connectomics is to construct a high-fidelity computer simulation of the brain (Whole Brain Emulation; Koene 2012). We can consider an interesting open question: Is it possible that we can have such a high-fidelity computer simulation of the brain but cannot understand what is going on in the simulation? This is a real possibility. Based on this, some might even argue that modeling and simulation do not give you any additional understanding about the phenomena that you are studying. However, we need to consider that simulations give us two very important tools: (1) full access to the system state (readout) and (2) full control over the system state (intervention). With a completely replicated simulation, we can conduct a full battery of experiments, including a unique opportunity to selectively damage or turn off parts of the system, which is an important requirement for inferring causality in a complex system (see Pearl 2001 for the importance of intervention for such an inference). Furthermore, high-fidelity simulations can lead to a rather exotic possibility of allowing the simulation itself to experiment on itself to objectively study subjective phenomena such as consciousness (note that whether brain simulations can cause mind is a whole separate issue; see, e.g., Searle 1980).

Some may argue that simulating the brain is not enough. That is, the entire body must be

simulated. This kind of argument can be based on philosophical grounds, e.g., the criticism of brain-body dualism by Bennett and Hacker (2003) (also see the counterpoint raised by Churchland 2005). However, the argument can also be based on practical grounds. All sensorimotor organs and the extensive peripheral nervous system form a major chunk of the animal nervous system, and these nervous networks define the environment-to-body interface. Without understanding this interface, it would be difficult to understand the function of the brain.

Finally, an important question is about the role of theory in the analysis of connectomics data. Connectomics research is data-driven by its nature, so one of the hopes is that data can lead us to principles of brain organization and function. However, due to the massiveness of the data, without theoretical guidance, it would be difficult to make progress. This is a classical chicken-or-egg problem: We want to study the connectome to get to the theory, but without theory we get lost in the data. There is some skepticism about connectomics research due to problems like this, but as argued by Lichtman and Sanes (2008), the human genome project had similar concerns yet the data ultimately led to spectacular scientific discoveries, and similar results are expected from connectomics. Since very specific theories can often be misleading unless grounded on detailed data, it would be better to start with broader perspectives, such as the importance of action and the sensorimotor loop (Llinás et al. 1994; Fuster 1997; Choe et al. 2007), the role of time and prediction (Choe et al. 2012), the evolutionary origin of brain (Humphrey 1992; Kwon and Choe 2009; Chung and Choe 2011), and the developmental processes that shape the brain (Weng et al. 2001; Miikkulainen et al. 2005).

Definition

The mouse connectome is a collection of all neuronal connections in the mouse brain, i.e., a complete wiring diagram of the mouse brain.

Detailed Description

The concept of connectome (Sporns et al. 2005; Seung 2012; Sporns 2012) has rapidly grown into a central theme in neuroscience and specifically in computational neuroscience and computational neuroanatomy. So far, as of 2013, the only existing connectome is that of the nematode *C. elegans* (White et al. 1986). Once obtained, the connectome of the mouse is expected to have significant scientific and clinical impact, due to (1) strong architectural and genetic similarities between the mouse and humans, (2) the extensive body of experimental studies involving the organism, and (3) the availability of a large array of transgenic, knockin, and knockout variants and molecular probes to infer function from the connectome structure (Chinwalla et al. 2002).

Acquisition of the Mouse Connectome

Rapid development in imaging technology in the past decade is taking us ever closer to the completion of the mouse connectome. See ► [“Physical Sectioning Microscopy”](#) for a detailed review of such imaging technologies.

Public Data Sources

Here, we will review existing public data sources relevant to mouse connectome research. As mentioned above, to date, a complete mouse connectome does not exist. The existing data collections focus on different aspects of the mouse connectome and are in many ways complementary to each other, especially due to the different scales and the size of the tissue volume represented in each data: cellular (or micro) connectome (sections [“Knife-Edge Scanning Microscope \(KESM\) Brain Atlas”](#) through [“Mouse Brain Architecture Project”](#) below) versus regional (or macro) connectome (section [“Electron Microscopy Data”](#) below).

Knife-Edge Scanning Microscope (KESM) Brain Atlas

The Knife-Edge Scanning Microscope (KESM) is a physical sectioning microscope that enables submicrometer-resolution imaging of whole small animal brains (Mayerich et al. 2008). The KESM Brain Atlas is an online atlas (<http://kesm.org>) at Texas A&M University that serves whole mouse (C57BL/6) brain data acquired using the KESM (Chung et al. 2011). Currently, three data sets are available, two from mouse brains stained with Golgi (neuronal morphology) and one with India ink (vasculature). The two Golgi data sets provide rich neuronal morphology data spanning the entire mouse brain with a voxel resolution of $0.6 \times 0.7 \times 1.0 \mu\text{m}$. Due to the sparse nature of the Golgi stain, exact synaptic connections and long-range projections are not visible in these data sets. However, the overall architectural plan of the

mouse brain can be studied, based on the diverse patterns of dendritic arbors across different regions of the mouse brain and major projection pathways such as the various commissures and the radiating projections within the striatum.

Allen Mouse Brain Connectivity Atlas

The Allen Mouse Brain Connectivity Atlas (<http://connectivity.brain-map.org>) provides axonal projection data from ~300 regions in the mouse brain, associated with C57BL/6 J mice and ~100 Cre driver lines backcrossed to the C57BL/6 J mice (Allen Institute for Brain Science 2012). For this atlas, conventional and viral tracers were used to label the projections, and serial two-photon tomography (Ragan et al. 2012) was used to section and image the prepared whole mouse brains. The resolution of the data sets is $0.3 \times 0.3 \mu\text{m}$ on the imaging plane, with a z-stack interval of 100 μm . The resulting image stacks are registered to the reference atlas of the Allen Mouse Brain Atlas and the Mouse Brain in Stereotaxic Coordinates (Paxinos and Franklin 2001). Quantitative data from the projections along with detailed annotations of the injection site are entered into an online neuroinformatics platform for public use. The platform also includes search and visualization tools for an extensive analysis of the axonal projection patterns in the mouse brain.

The Mouse Connectome Project

The Mouse Connectome Project (<http://mouseconnectome.org>) at the University of California, Los Angeles, hosts long-range projection data similar to the Allen Mouse Brain Connectivity Atlas. The collection hosts 245 injection cases (125 viewable at the moment, with a projected total case of 400 [as of July 2013]), with each case containing two injection sites using anterograde and retrograde tracers. All the brains used for data acquisition were that of the C57BL/6 J mice and were counterstained with a fluorescent

Nissl stain for cytoarchitectural registration. Injection sites were systematically chosen from a regular grid rather than anatomically identified regions. The prepared brains were sectioned coronally to 50 μm thick sections and imaged using a virtual slide scanner. All the data can be explored online using an interactive visualization tool called iConnectome. Detailed specimen preparation and data acquisition methods and case studies focusing on the pathways in the mouse olfactory bulb are available in Hintiryan et al. (2012). Latest work from the same project include a mouse neocortical connectivity atlas based on manual reconstruction (Zing et al. 2014).

Mouse Brain Architecture Project

The Mouse Brain Architecture Project (MPA, <http://brainarchitecture.org>) at the Cold Spring Harbor Laboratory also hosts long-range projection data similar to the Allen Mouse Connectivity Atlas and the Mouse Connectome Project. The MPA includes anterograde and retrograde tracer data from 235 regions in the mouse brain, with the majority of the injection sites in the cerebrum (218). The basic methodology is similar to that of the other long-range projection atlases: inject tracer in C57BL/6 mouse brain, slice (cryosection), whole-slide digital imaging (alternating slices processed with conventional histology and tracer detection, respectively), and make the processed data available online (Mitra 2012). However, one main feature distinguishes the MBA project from other atlases: the choice of injection coordinates. In MBA, the injection sites are determined by an algorithm to sample the brain in “the most homogeneous way compatible with separation of brain regions” (Grange and Mitra 2011). Injection sites in the cerebral cortex are selected based on a separate algorithm adapted to the geometry of the cortex.

Electron Microscopy Data

Electron microscopy (EM) data from selected regions of the mouse brain and nervous system are also available to the public.

The Open Connectome Project (<http://www.openconnectomeproject.org/>) hosts several EM image stacks, which include data from the mouse visual cortex (Bock et al. 2011). The data set was acquired using a custom Transmission Electron Microscope (TEM), spanning a volume $\sim 450 \times 350 \times 52 \mu\text{m}$, at a resolution of $<50 \text{ nm}$ in depth and $<5 \text{ nm}$ in the imaging plane.

The Whole-Brain Ultrastructural Mapping Project (<http://connectomes.org>) hosts EM data that spans an entire mouse coronal section at 80 nm voxel resolution, acquired using block-face electron microscopy. The data was made possible by a whole-brain EM staining method reported in Mikula et al. (2012).

Summary and Future Prospects

In this article, we reviewed mouse connectome data that are publicly available online. As we have seen, a complete connectome of the mouse is not yet available. However, data from multiple scales and different imaging modalities allow us to piece together an initial draft of the mouse connectome. Such a draft, although rough, can provide a valuable roadmap for the acquisition of the full mouse connectome.

Looking into the future, we can consider the acquisition of the raw connectome data as only a first step toward the understanding of mouse brain function. The immediate issue would be the geometric reconstruction of the neuronal morphologies and projections. Next, synaptic connections need to be established. Based on this, we can have a full wiring diagram. Inferring function from this wiring diagram would require a coordinated effort to integrate a vast amount of experimental research on mouse brain function – physiological, molecular, genetic, behavioral, and ecological – into the mouse connectome.

Context-Dependent Processing in Auditory Cortex

Israel Nelken

Edmond and Lily Safra Center for Brain Sciences,
The Hebrew University of Jerusalem,
Jerusalem, Israel

Definition

Context-dependent processing refers to the experimental finding that a neuron may respond to the same stimulus in different ways, depending on the state of the animal and/or the recent history of stimulation. Context dependence differs from plasticity in that the changes in response properties are fast and reversible.

Detailed Description

Examples of state-dependent modulation of neuronal responses abound in the auditory system. Thus, auditory responses may depend on whether an awake rat is engaged in a task (Otazu et al.

2009) or whether she is running or standing (Schneider et al. 2014). However, most studies of context-dependent processing in auditory cortex deal with a sensory context – the history of previous stimulation.

Context dependence in that sense occurs at multiple time scales. Already at the level of the auditory nerve, firing rate adaptation constitutes a simple form of context dependence, where context duration is a few ms or a few tens of ms (Eggermont 1985). An intensively studied example of context dependence consists of the suppression of the responses to a stimulus that is preceded shortly beforehand by another similar stimulus (often called “forward masking”). Forward masking at the level of the mechanical vibrations of the cochlea may account for most properties of psychoacoustical forward masking (Plack and Oxenham 1998). At the level of the inferior colliculus (IC), neural forward masking has been used to account for the precedence effect, in which the first arriving waveform dominates spatial perception (Litovsky et al. 1999).

As early as the IC, there are processes that adapt neuronal response properties to the statistics of the incoming sound streams (Dean et al. 2005). Thus, for example, in the IC (and to some extent even in the auditory nerve), sound level coding adapts to the statistics of the sound levels to which the animal is exposed. Roughly speaking, neurons shift their level responses so that the steepest part of their dynamic range overlays the sound level range that occurs most frequently. Similarly, temporal response properties of auditory neurons may change with changes in the noise level. For example, in the IC, at good signal-to-noise levels, neurons are mostly temporally band-pass, but in the presence of noise, they become low-pass (Lesica and Grothe 2008). Such changes may occur over a few hundreds of ms. Changes with similar flavor have been also documented in song birds (Nagel and Doupe 2006).

In auditory cortex, sensory context dependence may last as long and longer. For example, forward masking is prominent and may last hundreds of ms after the offset of the sound, far beyond psychoacoustical forward masking (Wehr and Zador 2005; Nakamoto et al. 2006). Such effects

have been characterized in terms of changes in gain – the same change in sound level produces different changes in the firing rate depending on some features of previous stimulation. Rabinowitz et al. (2011) described such effects in terms of contrast adaptation, while Ahrens et al. (2008) and Williamson et al. (2016) developed a concept of a context gain field that modulates the input gain of each frequency band by summing up information from nearby frequency channels, again with temporal extents of a few hundreds of ms.

A major type of context dependence studied in the vertebrate auditory system is called “stimulus-specific adaptation” (SSA). SSA is the reduction in the response to a repeated sound which does not generalize, or generalizes only partially, to other, even very similar sounds (Khouri and Nelken 2015). SSA is usually studied using oddball sequences composed of two stimuli, one of which is common (usually appearing in 80–95% of all tone presentations) and the other rare. By presenting two oddball sequences, with the role of the two stimuli switched, it is possible to compare the responses to the same stimulus when common and when rare. As a rule, the response to the same stimulus when rare is larger than when it is common. While SSA has been most often studied with tone pips of varying frequencies, it can be elicited by complex sounds as well (Nelken et al. 2013). SSA has been demonstrated in all major mammalian models of the auditory system and in nonmammalian vertebrates (barn owls) as well (Gutfreund 2012).

Two mechanisms that have been invoked to account for context sensitivity in auditory cortex are synaptic depression (Yarden and Nelken 2017) and firing rate adaptation (Malmierca et al. 2014). However, there is evidence for dependence on context that lasts many seconds, even tens of seconds (Asari and Zador 2009; Yaron et al. 2012), probably requiring mechanisms beyond these two.

At the long end, context sensitivity may be indistinguishable from fast plasticity, such as that documented in ferret auditory cortex (Fritz et al. 2003). In these experiments, the responses to a tone frequency have been rapidly and

selectively enhanced once that frequency became behaviorally relevant. These changes could occur within a minute or so, about the same time scale studied by Yaron et al. (2012).

In summary, context sensitivity in the auditory system is related to a number of separate processes that influence sound coding. While some of them are well studied, their overall effects on sound coding and the interactions between them are not, and this continuum of time scales, which span the range from milliseconds to minutes, remains an important frontier of auditory neuroscience.

Control of Aquatic and Terrestrial Gaits in Salamander

[Swimming and walking modes of the salamander](#)

Definition

Salamanders are amphibian animals that are capable of several aquatic and terrestrial gaits. These gaits are in large part controlled by central pattern generator (CPG) networks in the spinal cord. These networks can be modeled at several levels of abstraction from detailed models based on Hodgkin-Huxley type of neurons to abstract systems of coupled oscillators. The models have been instrumental in testing some hypotheses concerning gait generation and gait transition in the salamander. One of the main hypotheses is that the salamander CPG is constructed out of two main subnetworks: a lamprey-like swimming CPG for the axial musculature and slower CPGs for the limbs. Some of the models have been tested on a salamander-like robot and demonstrated their ability to make transitions between swimming and walking gaits by varying the level of tonic input applied to the CPGs.

Detailed Description

Locomotion in Salamanders

Salamanders are key animals from an evolutionary point of view. Their body plan is close to early terrestrial tetrapods (Cohen 1988; Edwards 1977), and they offer an interesting opportunity to study the transition from aquatic to terrestrial locomotion. Also they provide a useful link between popular animal models for studying vertebrate locomotion such as on one hand swimming animals like the lamprey and zebra fish and the other hand mammal tetrapods like the rat and cat.

In water, salamanders typically use an anguilliform swimming gait, i.e., a gait in which a traveling wave of lateral undulation is propagated all along the body from head to tail (see Fig. 3, bottom). The wavelength of the undulation is kept more or less constant and is close to one body length. The animal can change speed by modulating the frequency of the undulation, and the swimming frequency range is relatively high, e.g., 2.22–4.49 Hz (mean: 3.09 Hz) in *Pleurodeles waltl* (Delvolvé et al. 1997).

On ground, salamanders switch to either walking trot gaits (i.e., a gait in which diagonal pairs of limbs are moved in synchrony) or diagonal sequence walking gaits (see Fig. 3, top, for a walking trot). The frequencies are significantly lower, e.g., 0.58–2.17 Hz (mean: 1.23 Hz) in *Pleurodeles waltl* (Delvolvé et al. 1997), and in a given animal do not overlap with those of swimming. A review of the kinematics of salamander locomotion can be found in Karakasiliotis et al. (2013). Note that these two gaits are only two out of several others (the most frequent ones), and the animal exhibits a large movement repertoire.

Like many other vertebrate animals, the periodic and coordinated activations of axial and limb muscles are produced by central pattern generators (CPGs) located in the spinal cord (Grillner 1981). One can distinguish an axial CPG that activates the axial musculature in the trunk and tail and limb CPGs that activate limbs muscles. Both types of CPGs are composed of multiple-coupled oscillators, i.e., neural pools that can oscillate independently (Cheng et al. 1998,

2002) and that are coupled through projections between interneurons for producing coordinated activity patterns. For instance, it has been shown that surgically isolated segments and hemisegments of the axial CPG can produce rhythmic activity when pharmacologically activated (Ryczko et al. 2010a). Like the lamprey, the axial CPG is therefore a double chain of oscillators with reciprocal inhibition to produce left-right alternation. The limb CPG appears to be composed of a set of independent oscillators for flexor and extensor muscles, which are coupled with inhibition in parallel with weaker excitation (Cheng et al. 1998, 2002).

One can therefore hypothesize that the salamander axial CPG has been inherited from older, swimming vertebrates like the lamprey (Edwards 1977; Cohen 1988; Delvolvé et al. 1997; Ijspeert 2001) and that the circuit has been extended during evolution by phylogenetically more recent networks controlling the limbs. This hypothesis is consistent with the observation that salamanders and lampreys share the same anguilliform swimming mode. For homologies between lamprey and salamander, see Ryczko et al. (2010b).

A very interesting property of the salamander locomotor network is that electrical stimulation of the mesencephalic locomotor region (MLR, a part of the brain stem that controls the initiation and maintenance of locomotion; Dubuc 2009) in a decerebrated salamander will induce gait transitions depending on the level of stimulation (Cabelguen et al. 2003). The level of activation of that region determines the frequency and the mode of locomotion, with (slow) stepping movements at low intensity and (faster) swimming movements at high intensity (Cabelguen et al. 2003). Interestingly, a gradual increase of stimulation will lead to an abrupt switch of gaits when a certain stimulation threshold is reached. From a dynamical systems point of view, the MLR and spinal cord can therefore make a bifurcation between two very different regimes under the control of a simple tonic (i.e., non-oscillating) signal. Similar gait transitions under MLR stimulation have been observed in other vertebrates, e.g., transitions between walking, trotting, and galloping in decerebrate cats (Shik et al. 1966).

More detailed reviews of salamander locomotion and neurophysiology can be found in Chevallier et al. (2008), Karakasiliotis et al. (2013), and Bicanski et al. (2013a). While we now have a good grasp of the general organization and functioning of the salamander locomotor networks, many aspects still require more investigation and can strongly benefit from computational studies. In particular the following questions need to be addressed:

1. What are the mechanisms of rhythm generation and how are the local oscillators implemented, i.e., which types of interneurons are involved and how are they interconnected?
2. How are the oscillators of the whole network, i.e., axial and limb CPGs, coupled together?
3. How much does sensory feedback affect pattern generation?
4. What are the mechanisms of gait transition, in particular the switch between walking and swimming under MLR stimulation?
5. What is the interplay between multiple descending pathways and the spinal circuits that allows the animal to produce its large movement repertoire?

As we will see next, computational models can play a significant role in helping answering these questions and decoding the mechanisms of gait generation and gait transition. Note that many of these questions are relevant for vertebrate animals in general.

Using Numerical Models and Robots to Decode the Gait Generation Mechanisms

Different types of models have been developed to address the questions listed above. As will be briefly described later, the models vary in their level of abstraction, from detailed models composed of Hodgkin-Huxley-like neurons (Bicanski et al. 2013b) to integrate-and-fire neurons (Knüsel et al. 2013), to leaky-integrator neurons (Ijspeert 2001; Ijspeert et al. 2005), and to abstract models made of coupled phase oscillators (Ijspeert et al. 2007; Knüsel et al. 2013). Some models have

been tested together with a model of the body either in simulation or on board of a real robot (Ijspeert 2001; Ijspeert et al. 2005, 2007). See Bicanski et al. (2013a) for a review. The next sections will present two models, one based on coupled oscillators and one based on Hodgkin-Huxley-like neurons.

Oscillator Models of the Salamander Locomotor Circuit

Models made of abstract oscillators are useful to investigate and test hypotheses concerning the general topology of the couplings between neural oscillators and the mechanisms of gait transition, i.e., questions 2 and 4 as listed above.

These models are based on the assumptions that the rhythm generation ability of a local network of neurons can be represented by a simple oscillator model, without the need to model the

many individual neurons that compose the local network (in the order of several hundreds, the exact number is not known), and that the global dynamics of the coupled oscillator network is mainly dependent on high-level properties such as intrinsic frequencies of the oscillators, topology of inter-oscillator couplings, and strengths of couplings rather than on the local rhythm generation mechanisms. Such an approach is based on dynamical systems theory and has been useful to help understand the dynamics of the lamprey swimming network (Kopell 1995).

A model based on coupled oscillators was used to investigate the spinal mechanisms underlying the gait transition between stepping and swimming (question 4 above). To compare characteristics of the resulting gaits with those of the salamander, the mathematical model was coupled with a mechanical model of the body, i.e., an amphibious salamander-like robot *Salamandra robotica* (Fig. 1 right) (Ijspeert et al. 2007).

Control of Aquatic and Terrestrial Gaits in Salamander, Fig. 1 Configuration of a CPG model based on coupled oscillators (a) and salamander robot (b) (From Ijspeert et al. (2007)). The robot is driven by 10 DC motors, which actuate six hinge joints for the spine (black disks in the schematic view of the robot) and four rotational joints for the limbs (black cylinders). The CPG is composed of a

body CPG – a double chain of 16 oscillators with nearest neighbor coupling for driving the spine motors – and a limb CPG, four oscillators for driving the limb motors. The CPG model receives *left* and *right* drive signals d from the MLR region in the brain stem. The velocity, direction, and type of gait exhibited by the robot can be adjusted by modifying these two signals

The model represents the rhythmic activity of a local neural oscillator using the so-called amplitude-controlled phase oscillator. It is an oscillator with two state variables: the phase and the amplitude of oscillations. Its time evolution of an oscillator i is governed by the following equations:

$$\dot{\theta}_i = 2\pi v_i + \sum_j r_j w_{ij} \sin(\theta_j - \theta_i - \phi_{ij}) \quad (1)$$

$$\ddot{r}_i = a_i \left(\frac{a_i}{4} (R_i - r_i) - \dot{r}_i \right) \quad (2)$$

$$x_i = r_i (1 + \cos(\theta_i)) \quad (3)$$

where θ_i and r_i represent the phase and amplitude of the oscillator i , v_i and R_i determine the intrinsic frequency and amplitude (i.e., the frequency and amplitude toward which the oscillator converges when isolated), and a_i is a positive constant.

Oscillators are coupled together with diffusive coupling with a coupling weight w_{ij} and a phase bias ϕ_{ij} . The phase bias determines the phase lag that the coupling tends to induce between oscillators. The positive oscillatory signal x_i represents the periodic bursts produced by the oscillator. Such an oscillator is essentially a Kuramoto oscillator (Strogatz 2000) for the phase, extended with a critically damped second-order linear differential equation for the amplitude. An isolated oscillator will converge to a steady-state regime with sinusoidal output $x_i \propto \sin(v_i t + \theta_0)$ with frequency v_i and amplitude R_i : $x_i \propto (1 + \cos(v_i t + \theta_0))$.

The CPG model is used to test four hypotheses: (1) the axial CPG of the salamander is organized like that of the lamprey, i.e., as a double chain of oscillators that produces traveling waves when activated. (2) A strong coupling from limb oscillators to axial oscillators allows the limb oscillators to impose their (slower) frequency on the axial network when limbs are activated. (3) The limb oscillators cannot oscillate at high frequencies, i.e., they saturate and stop oscillating at high levels of stimulation. (4) Limb oscillators have a lower intrinsic frequency than the axial oscillators for the same level of drive.

Following these hypotheses, the model is made of 20 coupled oscillators, 16 for the axial CPG and

4 for the limb CPGs (Fig. 1, left). The topology and strengths of couplings satisfy hypotheses 1 and 2. The so-called saturation function is implemented to adjust the intrinsic frequency and amplitude of limb and axial oscillators depending on the drive (representing the descending stimulation coming from the MLR) according to hypotheses 3 and 4. The equations of the coupled differential equations are numerically integrated on board of a microcontroller of the robot.

When a low drive is applied to the model, it leads to salamander-like stepping movements, with periodic motions of the limbs that are in antiphase between fore- and hind limbs and with a standing wave of trunk and tail undulation (Fig. 2). When the drive is increased, both frequency and amplitude of the lateral undulation are increased leading to faster stepping. When the drive passes the saturation threshold of the limb oscillators, these stop oscillating, and the axial oscillators rapidly switch to a traveling wave regime. Also because of the saturation, the limb oscillators do not impose anymore slower frequencies, and the frequency of oscillations then rapidly increases, similarly to what is observed in the real animal. The model therefore correctly replicates the abrupt gait transition induced by MLR stimulation (Cabelguen et al. 2003). It also provides an explanation of why swimming frequencies are systematically higher than stepping frequencies in kinematic recordings of freely moving animals (Frolich and Biewener 1992; Delvolvé et al. 1997).

Interestingly, despite the robot being only an approximation of the salamander body (e.g., in terms of number of joints and the simplified limb design), the movements produced by the robot are strikingly similar to those of the animal both in water and on ground (Fig. 3). By adjusting the drive level, the speed of locomotion can be adjusted both during stepping and swimming, and rapid switches between the two gaits can be performed. By providing more drive to the axial oscillators on one side compared to the other, turning movements can be induced. The higher drive on one side leads to higher amplitude of bending toward that side.

Control of Aquatic and Terrestrial Gaits in Salamander, Fig. 2 Transition from stepping to swimming. The transition occurs when the drive applied to the CPG model is linearly increased (From Ijspeert et al. (2007)). Below the first threshold, the circuit is silent. Once passing this first threshold (at $t = 4$ s), the CPG produces stepping-like patterns with a standing wave in the axial CPG (*top*) and periodic activation of the limb CPGs (*second from top panel*). When reaching the limb saturation threshold ($t =$

20 s), the limb oscillators stop oscillating, and this releases a traveling wave in the axial CPG as needed for anguilliform swimming. The gait transition is accompanied by a jump in instantaneous frequency, with low frequencies for stepping and high frequencies for swimming (*third panel from top*). Note that the large variations in instantaneous frequencies at $t = 4$ s and $t = 20$ s are due to short transient periods during which the phases of oscillators rapidly change before reaching steady-state regimes

Hodgkin-Huxley Models of the Salamander Oscillatory Circuits

Models based on Hodgkin-Huxley (HH) neuron equations are useful to investigate the mechanisms of rhythm generation in the salamander (Question 1). Unlike the lamprey, the types of interneurons involved in the local oscillator networks of the salamander and the topology of their coupling are yet unknown. However, various experiments have shown that salamander and lamprey segmental circuits share many similarities (Ryczko et al. 2010b).

Models of the salamander segmental circuitry can therefore be developed with lamprey-like spinal hemisegments (i.e., oscillator networks on one side of the axial CPG) containing sparsely

connected excitatory and inhibitory neuron populations (Bicanski et al. 2013b). Hemisegments in the same segment are connected through both excitatory and inhibitory contralateral projections (Fig. 4). The model matches a large range of experimental findings, in particular the pharmacological stimulation by NMDA (*N*-methyl-d-aspartate) of isolated axial hemisegments and segments (Fig. 4, bottom). The model reproduces most of the effects of various pharmacological experiments (Ryczko et al. 2010a) that have been performed on isolated salamander spinal cords (e.g., the blockade of AMPA synapses, glycinergic synapses, calcium-activated potassium current, persistent sodium current, and h-current).

The model can not only replicate NMDA-induced oscillations, which are typically slower

Control of Aquatic and Terrestrial Gaits in Salamander, Fig. 3 Stepping and swimming gaits in the salamander and the robot. *Top two panels:* walking trot gait where the fore- and hind limbs are in antiphase and with the trunk and tail performing a standing wave. *Bottom two panels:* anguilliform swimming gait with the body making a lateral undulation traveling from head to tail (Adapted from the supplementary material of Ijspeert et al. (2007))

than *in vivo*, but also the range of *in vivo* frequency when receiving excitatory input from a population of simulated brain stem neurons (i.e., a more realistic way of stimulating spinal cord circuits). By slightly adjusting the conductances involved in burst termination, neural oscillators with different frequency ranges can be implemented, suggesting that the same circuit can be used both to represent slower limb oscillators and faster axial oscillators. When a slower limb oscillator is coupled to a faster axial oscillator, it can impose its slower frequency as needed

during stepping and similarly to the oscillator model above. The model therefore suggests that a lamprey-like segmental network can potentially serve as a building block for the axial and limb oscillators in salamanders.

Sensory Feedback, Rich Motor Skills, and Descending Pathways

The models above do not include sensory feedback, and it is likely that (multimodal) sensory feedback plays an important role in shaping the motor patterns and in adjusting their timing during locomotion. For instance, the difference of interaction forces between water and ground could possibly explain difference between traveling and standing waves in axial CPG during swimming and stepping. This was shown in a neuromechanical simulation that combined a simplified musculoskeletal model with a CPG model based on leaky-integrator neurons (Ijspeert et al. 2005). In the model, a simulated swimming salamander placed on dry ground tends to have lateral undulations that are close to a standing wave even when the CPG produces a traveling wave. In other words, the isotropic friction forces on dry ground imposed the standing wave of body movements. When sensory feedback from simulated stretch-sensitive cells was added to the circuit, the CPG activity was transformed into a standing wave that resembles the standing waves of EMG patterns recording during stepping on ground (Delvolvé et al. 1997). This illustrates how physical interaction with the environment together with sensory feedback can modulate CPG patterns.

Note that the coupled oscillator model described above (Ijspeert et al. 2007) relied on long-range couplings from limb to axial oscillators, with the forelimb oscillators sending projections to all trunk oscillators and the hind limb oscillators sending projections to all tail oscillators. Such a *global* coupling from limb to axial oscillators meant that a standing wave was imposed on the axial CPG as soon as the limb CPGs were active. Since then, experiments on isolated spinal cords have shown that the axial CPG can produce traveling waves even when the

Control of Aquatic and Terrestrial Gaits in Salamander, Fig. 4 Salamander neural oscillator model made of HH neurons. *Top*: topology of the circuit made of populations of excitatory (EIN) and inhibitory (CCIN) neurons. Each drawn neural unit represents a population of neuron models: 50 EINs and 30 CCINs per

hemisegment, i.e., a total of 160 neurons for the whole segmental network. *Bottom*: a representative average membrane potential trace in mV of the *left* and *right* hemisegmental EIN populations (Adapted from Bicanski et al. (2013b))

limb CPGs are rhythmically active (Ryczko et al. 2009). The frequencies of limb and axial CPGs are then identical and slow, supporting the idea of strong couplings from limb to axial CPGs (hypothesis 2 in the coupled oscillator model). But the fact that traveling waves are then observed instead of standing waves suggests that the coupling from limb to axial CPGs is only *local*, close to the girdles, and not global as in Ijspeert et al. (2007). It is therefore likely that the standing waves of EMGs during stepping are due either to sensory feedback or to modulation from descending pathways (rather than a central effect based on global couplings).

An important topic that remains to be addressed is how the salamander produces its large repertoire of movements (Question 5 above). In addition to anguilliform swimming and walking trots described above, the salamander can perform a large variety of movements such as backward walking, paddling limbs in phase, aquatic stepping, etc. The mechanisms underlying this large repertoire remain to be decoded, but it is most likely that they involve adding more descending pathways and more complex spinal circuits to the models presented above. Preliminary studies show that multiple different motor behaviors can be

generated by simply being able to activate subparts of the circuits differentially through different independent pathways (e.g., by providing different levels of drives to the neck, trunk, and tail oscillators in the axial CPG). But clearly the models will require modeling more complex circuits and more sensory streams to account for the richness of salamander motor skills. In particular the limb circuits are so far oversimplified and require more detailed studies. Continuing to combine experiments in neurophysiology together with modeling and robotic studies will be instrumental in making progress in this exciting field.

Definition

Models of respiratory regulation – as with many physiological control systems – have traditionally invoked the Sherringtonian reflex paradigm (Sherrington 1906) in which the response to any afferent input is assumed to follow a static stimulus–response relationship that adds to other stimulus–response relationships to produce the overall response. Such a reductionist analysis has set the foundation for our understanding of various respiratory control mechanisms, such as central and peripheral chemoreflex, lung inflation and deflation reflexes, and exercise reflex via various chemical

and mechanical afferent feedbacks and feedforward commands. Under this Sherringtonian framework, such feedback and feedforward controls are taken as a combination of simple reflex drives acting in parallel that are integrated algebraically by the brainstem respiratory controller in determining the resultant respiratory rhythm (inspiratory/expiratory duration) and motor pattern (tidal volume) in response to various exogenous and endogenous stimuli. However, this simplified reductionist framework of respiratory control has been challenged by recent evidence indicating that such stimulus–response relationships are not merely mediated by static reflexes in the form of classical proportional feedback and feedforward controls but may involve adaptive neural mechanisms that conform to adaptive control systems in modern engineering control theory.

According to Sherrington (1906), reflexes are animal instincts evolved through natural selection to serve specific survival purposes in adaptation to challenging environments, hence the term “adaptive reflex.” On the other hand, it is now well recognized that many reflexes in lower animals (e.g., Aplysia gill and siphon withdrawal reflex) and mammalian higher brain mechanisms (e.g., eye-blink reflex) may also adapt in real time to modify the stimulus–response relationships through nonassociative and associative learning, two forms of use-dependent (activity-dependent) neural plasticity that contribute importantly to brain intelligence. This entry will focus on the roles of nonassociative and associative learning in adaptive modulation of chemoreflex, mechanoreflex, and exercise reflex control of breathing.

This entry is organized as follows. The next section presents the notion of *nonassociative learning* in respiratory control. Nonassociative learning is the progressive decrease (short-term depression, STD) or increase (short-term potentiation, STP) in the evoked response upon continued or repetitive afferent stimulation, evidencing use-dependent plasticity (Poon and Schmid 2012). Two traditional forms of nonassociative learning (*habituation* and *sensitization* evidencing STD and STP, respectively) have been extensively studied in the classic experiment of Aplysia gill and siphon withdrawal reflex (Hawkins et al.

1998). A third form of nonassociative learning called “*desensitization*” – also evidencing STD but is expressed in a secondary pathway – was first discovered in the pontine modulation of the Hering–Breuer reflex in rats (Siniia et al. 2000). The three forms of nonassociative learning – habituation, sensitization and desensitization – have been shown to have significant computational relevance and can be formulated as a *neural integrator/differentiator* that modulates the stimulus–response relationship in a time-dependent manner.

The third section discusses the role of *associative learning* in respiratory control. Associative learning such as classical (Pavlovian) conditioning differs from nonassociative learning in that the plasticity is not only use dependent but also pairing specific, requiring the interaction of two coincident afferent inputs called the conditioned and unconditioned stimuli. A canonical example of classical conditioning is the mammalian eye-blink reflex (Thompson and Steinmetz 2009). Another form of associative learning is operant conditioning (also called instrumental conditioning or reinforcement learning), in which the response to a stimulus may be modified by feedback of the resultant response in a closed loop in order to optimize certain performance measure (Hawkins et al. 2006). Experimental observations suggest that associative learning may play an important role in modulating the respiratory controller gain through integration of a variety of respiratory afferent information. This suggests that the respiratory controller may not simply add multiple stimuli linearly but may integrate them in a nonlinear, time-dependent manner to bring out an optimal response in the face of changing environmental challenges. Such optimal respiratory control suggests a close correlation between homeostatic regulation in physiology and the internal model principle in engineering (Poon et al. 2007) – which states that a feedback regulator under external disturbances may maintain regulation and stability provided a suitably reduplicated (internal) model of the disturbance signal is adapted in the feedback path (Francis and Wonham 1975). The notion of internal model is now well recognized in sensorimotor integration

(Davidson and Wolpert 2005; Tin and Poon 2005). This section concludes with a discussion of the relevance of internal model learning in respiratory control.

Detailed Description

Nonassociative Learning in Vagal–Mechanical Reflex and Chemoreflex Adaptation

Nonassociative learning with activity-dependent STP and STD of neurotransmission is prevalent in respiratory control. For instance, during hypoxia or sustained carotid sinus nerve stimulation, STP is evidenced by a progressive increase in the amplitude of respiratory motor response, followed by a gradual decay (afterdischarge) of the heightened response upon removal of the stimulus (Poon et al. 1999; Song and Poon 2009b). Such neural plasticity phenomena have important computational implications.

Nonassociative Learning as Neural Integrator and Differentiator

Functionally, the temporal patterns of STP and STD in response to a stimulus can be modeled respectively as a neural integrator and neural differentiator, or equivalently a low-pass and high-pass filter (Poon and Siniaia 2000). This analogy provides a strong mathematical foundation that underpins nonassociative learning in the perspective of adaptive control. Numeric integration and differentiation are elemental calculus operations. They also underlie all temporal dynamics and kinematics phenomena in Nature. An analog integrator or differentiator is any physical process with observable input and output signals that demonstrate integral or differential transformation in real time, respectively. Analog integrators and differentiators are limited by their *leakages*, i.e., physical bypasses that offset the integration and differentiation processes. Leaky integrators or low-pass filters are commonly used in electrophysiology experiments to obtain a moving time average of neuronal firing, which gives an analog “neurogram” of spike frequency as an output.

In the time domain, a leaky integrator’s response to a constant-step input exhibits

exponential saturation during on-transient and exponential decay during off-transient, whereas the corresponding response of a leaky differentiator demonstrates exponential decay from an initial overshoot during on-transient and exponential recovery from rebound undershoot during off-transient (Fig. 1a). As such, STP and STD are closely related to neural integrator/differentiator as they display characteristic integral/differential responses. A first-order neural integrator or differentiator can be readily described by the following state-space model (Poon and Young 2006):

$$\begin{aligned}\dot{x} &= -ax + bu \\ y &= cx + du\end{aligned}\quad (1)$$

where x and $\dot{x}$ are the state variable and its time derivative, respectively; y and u are the output and input of the integrator or differentiator; a , b , c , and d are the system parameters with $a > 0$ to guarantee stability.

With a constant-step input, $u = u_0$ for $0 < t \leq T$, where T is the duration of stimulation, Eq. 1 can be solved analytically for $x(t)$ (and hence $y(t)$) assuming $x(0) = 0$:

$$y(t) = du + \frac{cbu}{a}(1 - e^{-at}) \text{ for } 0 < t \leq T \quad (2)$$

The response $y(t)$ corresponds to a neural integrator if both terms on the right-hand side of Eq. 2 have the same sign, or a neural differentiator if they have opposite signs. Similarly, their afterdischarge during off-transient can be modeled by the following equation:

$$y(t) = (y(T) - y(0))e^{-at} \text{ for } y > T \quad (3)$$

Hence, neural integrator and differentiator can be characterized by the above exponential functions in the time domain. Higher-order integrator and differentiator can be achieved by combining multiple exponentials with different gains and time constants.

From linear time-invariant systems theory, neural integrator and differentiator can also be expressed in frequency domain using Laplace transform. In this regard, they perform low-pass and high-pass filtering to the input signal. The

Control of Breathing, Integration of Adaptive Reflexes, Fig. 1 Time and frequency response characteristics of integrator (*left panels*) and differentiator (*right panels*). (**a**) The temporal response of a leaky integrator to a constant-step stimulus (horizontal bar) consists of abrupt reflex increase/decrease of the response at stimulus onset/cessation followed by exponentially increasing/decaying (potentiation/afterdischarge) on-/off-transients. A leaky differentiator has similar reflex components but with exponentially decaying/rebound-increasing (accommodation/aftercharge) on-/off-transients, which are opposite to those of an integrator (*overlying dotted lines*). In both cases the off-transients may be rectified, with the response becoming monophasic (not shown) instead of biphasic. The time scales chosen are typical of oculomotor integrator and respiratory integrator. (**b**) In the

frequency domain, an integrator/differentiator behaves like a low-pass/high-pass filter. The passband in both cases is the frequency range where the transmission gain (normalized to unity) is highest and relatively constant. The high and low cutoff frequencies (*vertical dotted lines*) of these filters are inversely proportional to the time constants of the corresponding integrator and differentiator shown in **a**. (**c**) Examples of RC integrator ($C = 3.77$, $R_1 = 1.60$, $R_2 = 24.0$, $R_3 = 0.73$) and differentiator ($C = 1.0$, $R_1 = 1.75$, $R_2 = 24.0$, $R_3 = 10.2$) circuits with a current source (I_s) input and voltage (V_0) output. Units are arbitrary and RC values correspond to parameter values as defined in Eq. 1 for integrator ($a = 0.125$, $b = 0.125$, $c = 1$, $d = 0.5$) and differentiator ($a = 0.125$, $b = 0.125$, $c = -1$, $d = 1.5$) (Adapted from Poon and Young (2006))

time constant of a leaky integrator or differentiator is inversely proportional to the cutoff frequency of the equivalent low-pass or high-pass filter, respectively. In addition to frequency filtering, a leaky integrator/differentiator also introduces phase

shift (phase lag/phase lead) in the input–output relationship (Fig. 1b, c).

An integrator or differentiator that sustains an off-transient response with short-term memory decay upon removal of the stimulus is said to be

biphasic (or else, monophasic); it is termed inverted if the gain is negative. Under these broad definitions, nonassociative learning may be classified into four basic forms depending on whether the corresponding neural integrator or differentiator response is monophasic or biphasic (Poon and Young 2006). The STD or STP induced in a *primary* stimulus–response pathway (i.e., one that is directly activated by the primary stimulus) is necessarily monophasic, in that all reflex and adaptation effects mediated by that pathway must vanish abruptly and any associated memory effects become latent once the primary stimulus ceases (Fig. 2). *Habituation* and *primary sensitization* are monophasic STD and STP expressed in the primary stimulus–response pathway. The monophasic effects reflect the fact that the primary pathway is disfacilitated (gated off) once the primary stimulus ceases. Hence, habituation and primary sensitization act not only as a high-pass or low-pass filter in the frequency domain but also as a temporal filter in the time domain that

gates off any residual memory effect of the STD and STP in the primary pathway once the primary stimulus is removed.

Alternatively, the primary stimulus may induce STP or STD of neurotransmission indirectly in a collateral (*secondary*) pathway which is driven by another (secondary) input (Fig. 2). In this event the resulting integrator/differentiator response is *biphasic* with a post-stimulus short-term memory response, as the secondary input keeps the secondary pathway active after the primary stimulus ends. Such a post-stimulus response provides a simple marker for discriminating the memory effects in the primary and secondary pathways. The nonassociative learning effects corresponding to STD and STP mediated by a secondary pathway have been termed *desensitization* and *secondary sensitization*, respectively, in contradistinction to their counterparts (habituation and primary sensitization) that are mediated by the primary pathway.

A primary stimulus may induce STP and/or STD in the primary and secondary pathways

Control of Breathing, Integration of Adaptive Reflexes, Fig. 2

Compound neural integrator and differentiator models. Boxes show model simulations in arbitrary units and parameter values. (a) Primary differentiator–secondary integrator is realized by activity-dependent habituation–sensitization in corresponding primary–secondary pathways. Step application of primary input at a constant firing rate (*inset*) induces synaptic STD and STP (*filled* and *open inner triangle*) in primary and secondary pathway, respectively, with corresponding temporal differentiation and integration of the transmitted signals (*upper* and *lower boxes*). Primary differentiator is monophasic (with abrupt termination of response due to auto-chopping at end of stimulus train), whereas secondary

integrator is biphasic. Resultant response (*last box*) at output neuron shows a compound differentiator–integrator characteristic. (b) A double integrator may arise from STP in both primary and secondary pathways. (c) A double differentiator is similar to a double integrator but with STD instead of STP in both pathways. (d) A primary integrator–secondary differentiator can be realized in a similar fashion with a STP–STD combination. Structurally, primary differentiator (a, c) and secondary differentiator (b, d) are comprised of the primary reflex in conjunction with an inverted primary and secondary integrator, respectively, demonstrating the complementarities of integrator and differentiator (Adapted from Poon and Young (2006))

simultaneously to form compound integrator/differentiator. The dynamical order of a compound integrator/differentiator is the number of integrators/differentiators it is composed of, and its memory order is the number of component integrators/differentiators that are biphasic with short-term memory. The four possible second-order compound integrator/differentiator configurations are summarized in Fig. 2. Under this framework, the classical dual-process theory of nonassociative learning with concurrent habituation and secondary sensitization (Groves and Thompson 1970) is a special case of the second-order compound integrator/differentiator structure.

Short-Term Depression of Vagally Mediated Hering–Breuer Reflex

The classic Hering–Breuer inflation reflex describes the inspiration inhibition and expiration prolongation consequent to lung inflation, which is sensed by slowly adapting pulmonary stretch receptors in the airways and conveyed by the vagus nerve to the respiratory controller. This “reflex” is presumed to protect the lungs from potential damages due to overexpansion. However, new data accumulated over the past decade suggest that such a reflex is not static but is dynamic and adaptive, conforming to non-associative learning (MacDonald et al. 2009; Poon et al. 2000; Siniiaia et al. 2000).

During sustained lung inflation or electrical vagal stimulation in vagotomized rats, the immediate Hering–Breuer reflex response is countered by an ensuing STD that gradually lessens the initial lengthening of expiratory duration (T_E) and decrease of respiratory frequency (f_R). This is followed by a rebound shortening of T_E and increase of f_R upon termination of lung inflation or vagal stimulation before these post-stimulus STD responses gradually die out. The on- and off-transient STD responses in T_E and f_R resemble a biphasic differentiator. In both cases, the on-transients are best fitted by second-order exponential functions, while the off-transients are best fitted with a first-order exponential. The curve-fitting results suggest a second-order differentiator with monophasic STD (habituation) in the primary pathway and biphasic STD (desensitization) in a

secondary pathway (Fig. 2). Studies show that the biphasic STD component is abolished by NMDA receptor blockade or lesioning of the Kölliker–Fuse nucleus in the pontine pneumotaxic region in vagotomized rat, but similar interventions have no effect on the monophasic STD component (Poon et al. 2000; Siniiaia et al. 2000). The latter is thought to be mediated by relay neurons in the nucleus tractus solitarius, which demonstrate afferent-induced phasic STD that is NMDA receptor independent as well as long-term depression that is NMDAR receptor dependent (Zhou et al. 1997). The biphasic STD component with a post-stimulus rebound response that is dependent on NMDA receptor activity effectively discriminates the adaptive modulation of the Hering–Breuer reflex due to desensitization in the secondary (pontine) pathway from that due to habituation in the primary pathway. Pontine desensitization of the Hering–Breuer reflex in vagal-intact animals plays an important role in restoring entrainment of the respiratory rhythm to cyclical mechanical ventilation upon changing ventilator frequency and/or end-expiratory airway pressure (Dutschmann et al. 2009; MacDonald et al. 2007).

Short-Term Potentiation and Depression of Peripheral Chemoreflex

In addition to pulmonary stretch receptor afferents mediated by the vagus nerve, the respiratory control system also senses arterial partial pressures of (CO_2 (P_{aCO_2})) and O_2 (P_{aO_2}) and arterial pH through central and peripheral chemoreceptors in order to regulate blood gas concentrations and acid–base balance to maintain homeostasis. Abrupt exposure to hypoxic gas or brief electrical stimulation of the carotid sinus nerve (CSN) in animal models elicits complex peripheral chemoreflex response of inspiratory and expiratory variables that vary in a time-dependent manner (Poon et al. 1999, 2000; Song and Poon 2009b). These include a biphasic STP of inspiratory amplitude (with post-stimulus afterdischarge) and STD-like shortening of inspiratory duration (T_I) resulting in a STP-like progressive increase of f_R , as well as rapid shortening of T_E followed by a biphasic STP-like lengthening of T_E , resulting in post-hypoxic decline of respiratory frequency. The hypoxia-/CSN-induced

STP and STD of inspiratory variables resemble a biphasic neural integrator, whereas the corresponding STP of the T_E response in combination with an initial rapid shortening of T_E at the onset of hypoxia/CSN stimulation resembles a biphasic neural differentiator. These nonassociative learning effects provide low-pass and high-pass filtering of the peripheral chemoreceptor afferent input as discussed in the previous section.

Detailed analysis of the dynamics of the peripheral chemoreflex response to CSN stimulation delivered repetitively breath-by-breath during either the inspiratory or expiratory phase of the respiratory cycle reveals that peripheral chemoafferent signaling is relayed by parallel integrator/differentiator central pathways that independently modulate inspiratory amplitude, T_I and T_E with varying time constants (Young et al. 2003). These include biphasic fast–slow compound integrator pathways that mediate the successive augmentation of inspiratory amplitude and shortening of T_I , and biphasic fast–slow compound integrator/differentiator pathways that mediate the initial shortening and subsequent prolongation of T_E . These biphasic integrator/differentiator pathways also account for the off-transients of all these response components.

Blockade of NMDA receptor slows down the dynamics of the inspiratory-related neural integrators (Poon et al. 1999) and abolishes the slow expiratory-related neural differentiator response (Poon et al. 2000). Lesioning of lateral parabrachial nucleus selectively attenuates the rapid shortening of T_E during hypoxia, but presents no observable effects on the hypoxic response of other respiratory variables (Song and Poon 2009b). Similarly, lesioning of lateral parabrachial nucleus selectively attenuates the shortening of T_E and increase of inspiratory amplitude during hypercapnia, but presents no observable effects on the hypercapnic response of T_I (Song and Poon 2009a).

Long-Term Facilitation of Vagal–Mechanical Reflex and Peripheral Chemoreflex

In addition to short-term adaptive modulation of vagal–mechanical reflex and peripheral chemoreflex with STP and STD in primary and

secondary pathways following sustained afferent stimulations, long-term adaptive modulation of these reflexes may ensue when the afferent activations become repetitive. Specifically, repeated exposures to alternating episodes of hypoxia and hyperoxia in humans and animal models may induce long-term facilitation of respiratory (phrenic) motor output as well as hypoglossal (particularly genioglossal) and laryngeal adductor motor outputs that serve to increase upper airway patency (Fuller et al. 2000; McGuire et al. 2007; Xing et al. 2013). Similarly, episodic modulation of vagally mediated mechanical feedback induces long-term facilitation of hypoglossal motoneuron activity (Tadjalli et al. 2010). It is believed that such long-term adaptive modulations of the vagal respiratory reflex and peripheral chemoreflex are protective responses to obstructive sleep apnea, which is characterized by repeated episodes of hypoxemia and disruption of vagal feedback.

Associative Learning in Vagal–Mechanical Reflex and Chemoreflex Adaptation

In associative learning, the learning process is dependent on the pairing of two coincident inputs. Its significance in respiratory control has traditionally been underappreciated in favor of the Sherringtonian framework. However, recent evidence increasingly points to the existence of associative learning in respiratory control similar to classical studies in *Aplysia* (Glanzman 1995) and cerebellum (Thompson 1988). Specifically, vagal–mechanical input and central and peripheral chemoafferent inputs may indeed interact associatively (rather than linearly) in modulating the resultant ventilatory output.

Associative Learning in Central–Peripheral Chemoreceptor Interaction

A generally accepted simplification in current mathematical models of respiratory control is that feedback signals from central and peripheral chemoreceptors add linearly to determine the total “reflex” response (Cunningham et al. 1986; Gray

1946; Grodins et al. 1954), an assumption that is supported by indirect evidence (e.g., (Mardimae et al. 2012)). However, a significant number of reports in the literature present conflicting observations indicating that the interaction of central and peripheral chemoreceptor inputs may not be purely additive but could range from hypoadditive on one end of the spectrum to hyperadditive on the other. A recent study in awake dogs (Blain et al. 2010) provides one of the strongest evidence for hyperadditive peripheral–central chemoreceptor interaction, by abruptly stimulating the central chemoreceptor while holding the peripheral chemoreceptor activity constant at varying background levels. On the other hand, other studies (Day and Wilson 2007, 2009; Tin et al. 2012) demonstrate hypoadditive interaction when the peripheral chemoreceptor is stimulated while the central chemoreceptor activity is held constant at varying background levels. In particular, (Tin et al. 2012) showed that the responses in inspiratory amplitude and T_E (and hence f_R and neural ventilation) to hypoxia varied inversely with the background CO_2 level in spontaneously breathing (vagal–intact or vagotomized) and mechanically ventilated rats. The results show a hypoadditive hypercapnic–hypoxic interaction *in vivo* that resembles the reported hypoadditive central–peripheral chemoreceptor interaction *in situ* for these respiratory variables in the rat (Day and Wilson 2007, 2009), regardless of differences in vagal feedback, body temperature and ventilation method.

Collectively, these reports point to a complex nonlinear interaction of peripheral and central chemoreceptor inputs that contradicts the traditional Sherringtonian paradigm. The mechanism and site of such nonlinear interaction remain to be investigated.

Associative Learning in Mechanical–Chemical Interaction

Another limitation of the classical chemoreflex/mechanoreflex model under the Sherringtonian paradigm is that it cannot explain the control of ventilation during muscular exercise. In this case, ventilation increases directly with increasing metabolic demands (in terms of metabolic

CO_2 output, $\dot{V}_{CO_2}$) without any appreciable increases in P_{aCO_3} and arterial pH, i.e., without apparent activation of the chemoreflex mechanism. This discrepancy has led to the postulation of some exercise-induced feedforward signal that drives respiratory ventilation in proportion to metabolic demands with near constancy of arterial CO_2 and pH levels (Grodins et al. 1954). However, despite extensive search over the past century, none of the hypothesized feedforward or feedback mechanisms has been demonstrated conclusively as the true “exercise stimulus” that is obligatory to exercise hyperpnea (Poon et al. 2007). Much of the confusion lies in the fact that feedback mechanisms such as chemoreflex and skeletal muscle afferent feedback exert only transient effects on the exercise ventilatory response but do not materially contribute to the steady-state exercise hyperpnea response (Poon and Tin 2013). This persistent lack of conclusive evidence of a feedforward exercise stimulus as hypothesized under the Sherringtonian reflex paradigm raises serious questions regarding the validity of such oversimplified models for exercise hyperpnea.

Optimization Model of Exercise Hyperpnea and CO_2 Breathing

In contrast to Sherringtonian reflex, it has long been conjectured that many respiratory control phenomena may boil down to the general idea of optimality implied in natural selection (Priban and Fincham 1965). Poon (1987) first introduced the following mathematical cost function to integrate the chemical and mechanical components of breathing:

$$J = J_c + J_m = [\alpha(P_{aCO_3} - \beta)]^2 + \ln \dot{W}_o^2 \quad (4a)$$

$$\text{where } \dot{W}_o = \dot{V}_E^2 / (1 - \dot{V}_E / \dot{V}_{max})^2 \quad (4b)$$

The terms J_c , J_m in Eq. 4a represent the competing chemical and mechanical costs of breathing (α , β are parameters) in conformance to Steven’s power law and Weber–Fechner law of psychophysics, respectively. The term $\dot{W}_o$ that defines J_m is a measure of the work rate of

breathing as perceived by the respiratory controller subject to the mechanical limitation of the respiratory system. This is given by the mechanical plant equation (4b), where $\dot{V}_{max}$ is the maximal ventilation that could be sustained by the respiratory pump and the factor $(1 - \dot{V}_E/\dot{V}_{max})^2$ represents the pump's neuromechanical efficiency. The chemical cost J_c is a function of total chemical feedback. At rest and during moderate exercise it is determined primarily by P_{aCO_2} , which is constrained by the pulmonary gas exchange (chemical plant) equation:

$$P_{aCO_3} = P_{ICO_3} + \frac{863\dot{V}_{CO_2}}{\dot{V}_E \times \left(1 - \frac{V_D}{V_T}\right)} \quad (5)$$

In Eq. 5, V_D/V_T is the physiological dead space-to-tidal volume ratio and is a measure of the inefficiency of pulmonary gas exchange, and P_{ICO_2} is the partial pressure of CO_2 in the inspired air during CO_2 inhalation ($P_{ICO_2} = 0$ when breathing room air).

The optimal total ventilation $\dot{V}_E$ is one that minimizes J (Eq. 4a) subject to the pulmonary gas exchange process (Eq. 5) and mechanical constraint (Eq. 4b), thus weighing the chemoafferent feedback against respiratory mechanical feedback, giving:

$$\dot{V}_E = \frac{\dot{V}_{E0}}{1 + \dot{V}_{E0}/\dot{V}_{max}} \quad (6a)$$

$$\text{where } \dot{V}_{E0} = 863\alpha^2(P_{aCO_3} - \beta) \times \frac{\dot{V}_{CO_2}}{\left(1 - \frac{V_D}{V_T}\right)} \quad (6b)$$

Equation 6 simulates the linear $\dot{V}_E = P_{aCO_3}$ relationship during CO_2 inhalation and proportional $\dot{V}_E - \dot{V}_{CO_3}$ relationship during exercise at constant P_{aCO_3} level. Thus, the optimization model successfully reproduces normocapnic exercise hyperpnea and hypercapnic CO_2 response by simply adopting an optimal control law (Eq. 4a) in place of the Sherringtonian reflex control law, without the need of an explicit feedforward exercise stimulus. In more general terms, the model addresses the important question of how the respiratory controller balances multiple competing objectives in order to optimize the work of breathing while striving to maintain homeostasis of arterial CO_2 and pH levels in a unified framework (Fig. 3). The form of the optimal solution (Eq. 6a & 6b) implies that the respiratory controller is responsive to an apparent metabolic CO_2 load $\dot{V}_{CO_3}/(1 - V_D/V_T)$ which tracks not only the actual metabolic CO_2 load $\dot{V}_{CO_3}$ but also the inefficiency of pulmonary gas exchange (V_D/V_T) that adds to the overall challenge of CO_2 elimination. This is in close agreement with the observation of heightened exercise ventilation at normal P_{aCO_3} in patients with increased physiological V_D/V_T , such as in congestive heart failure. The

Control of Breathing, Integration of Adaptive Reflexes, Fig. 3 Two views for respiratory control. (a) Classical reflex model assumes additive, reducible, and superposable characteristics of chemical, mechanical, and

exercise stimuli. (b) The optimization model integrates various afferent-efferent signals in a single model to characterize the complex interactions among these signals (Adapted from Poon et al. (2007))

controller's responsiveness to an apparent metabolic load that is influenced by inefficiency of pulmonary CO_2 elimination caused by physiological V_D/V_T is indicative of its ability of cognition and perception (Poon and Tin 2013). This is analogous to temperature sensing, where the perceived (or "real-feel") temperature is determined not only by the ambient temperature but also by environmental factors (humidity, wind chill, etc.) that affect body heat dissipation.

On the other hand, for any sizable external dead space load added in series with the airway, CO_2 elimination is also impaired by an elevated series V_D/V_T with resultant increase in the apparent metabolic CO_2 load like in congestive heart failure patients. However, because the increase in V_D/V_T now comes with rebreathing of dead space CO_2 , the controller may (at the beginning of each inspiration) mistake the dead space load for an airway CO_2 load (at $P_{ICO_3} \approx P_{aCO_3}$) that remains until the dead space is cleared toward late inspiration. This ambiguity may render the controller with an illusion of a *virtual* $P_{ICO_3}(\hat{P}_{ICO_3})$, which amounts to a virtual airway CO_2 load (Poon and Tin 2013). Hence, the effect of external dead space loading is equivalent to a combination of airway CO_2 loading and parallel dead space loading. Such illusive perception caused by CO_2 rebreathing provides a plausible explanation of the hypercapnic effect of dead space loading as opposed to the eucapnic state of increased physiological V_D/V_T in congestive heart failure.

In addition, Eq. 6b predicts a synergetic CO_2 –exercise interaction such that the slope of the $\dot{V}_E - \dot{V}_{CO_3}$ relationship is increased at increasing P_{aCO_3} levels while inhaling CO_2 , as demonstrated experimentally (Poon et al. 2007; Poon and Tin 2013). In contrast, the traditional Sherringtonian reflex model would predict an additive CO_2 –exercise interaction with a parallel shift of the $\dot{V}_E - \dot{V}_{CO_3}$ curve by CO_2 inhalation instead (Poon 1987). On the other hand, Eq. 6a shows that the magnitude of CO_2 –exercise interaction is also influenced by mechanical constraints. The term $\dot{V}_{max}$ in Eqs. 4 and 6a represents a hypothetical maximum ventilation that can be sustained by the respiratory muscles, such that the effect of mechanical limitation intensifies as $\dot{V}_E$ approaches

$\dot{V}_{max}$ resulting in a less than multiplicative CO_2 –exercise interaction at increasing $\dot{V}_E$ levels (Poon 1987). In this event, the resultant $\dot{V}_E - \dot{V}_{CO_3}$ curve would demonstrate an apparent additive component with a positive y-intercept. Hence, mechanical limitation due to a finite $\dot{V}_{max}$ provides a plausible explanation of the apparent additive CO_2 –exercise interaction component found in experiments that include moderate to high exercise $\dot{V}_E$ levels (Poon and Greene 1985) or in patients with pronounced ventilatory limitations (Paoletti et al. 2011).

Optimization Model of Mechanical Load Compensation

A remarkable property of the respiratory controller is its capability to compensate for ventilatory loading and unloading at rest and during moderate exercise, a phenomenon known as ventilatory load compensation. In normal subjects, this is achieved by adopting an optimal respiratory pattern that minimizes the increases in mechanical work rate of breathing caused by the ventilatory load, provided the latter is not mechanically limiting at the ventilatory levels of interest (i.e., at $\dot{V}_E \ll \dot{V}_{max}$) (Poon 1987, 1989a, b). This capability is also evidenced in patients with early stages of certain cardio respiratory diseases such as pulmonary fibrosis and emphysema. The optimization model provides a conceptual framework for understanding this behavior. To model the integrative control of $\dot{V}_E$ and respiratory pattern, Eq. 4a has been extended by expressing $\dot{W}_o$ explicitly in terms of the isometric respiratory driving pressure $P(t)$ (Poon et al. 1992). The mechanical plant in this case is defined by the following equation of motion:

$$P(t) = \dot{V}(t)R_{rs} + V(t)E_{rs} \quad (7)$$

whereby all ventilatory variables can be derived successively from the $P(t)$ waveform as follows:

$$P(t) = \dot{V}(t), \quad V(t) \rightarrow V_T, V_I, T_E \rightarrow \dot{V}_E \quad (8)$$

where R_{rs} , E_{rs} are respectively the total (extrinsic and intrinsic) respiratory resistance and elastance; $\dot{V}(t)$, $V(t)$ are instantaneous respiratory airflow and volume; and T_I and T_E are inspiratory and

expiratory durations. The resultant $\dot{V}_E$ is given by the variables V_T , T_I and T_E . This integrated model captures both the optimal ventilatory response characteristics of Eq. 6 and the corresponding optimal respiratory pattern. The strength of ventilatory load compensation is dependent on the type and magnitude of the ventilatory load relative to those of the background ventilatory stimulus. The parameters R_{rs} and E_{rs} can explicitly model the effects of resistive, elastic, and threshold loading, which have been studied singly and in combination, as well as under the influence of chemical stimulus and exercise (Poon 1989a, b; Sidney and Poon 1995). Computer simulations with the optimization model have proved to be consistent with the experimental observations (Poon et al. 1992). In all cases, ventilatory loading provokes compensatory inspiratory, postinspiratory, and expiratory motor responses that fully or partially restore $\dot{V}_E$ to the control level in normal or disease states or when ventilation is stimulated by chemical or exercise inputs.

Internal Model Paradigm in Respiratory Control

Traditional Sherringtonian reflex models of homeostatic regulation rely mainly on feedback, feedforward, and set-point operations. These classical control engineering schemes have limited predictive power for complex behaviors, such as integrative physiological control at multiple levels of organization, and are nonrobust to disturbances (Poon 1996). In contrast, the optimization model suggests that the respiratory controller may be self-adapting, continuously maintaining optimality in the presence of unknown disturbances.

In this context, the homeostatic regulation problem in physiology is closely related to the internal model principle in modern control systems engineering, which states that a feedback regulator under external disturbances may maintain regulation and stability provided a suitably reduplicated model of the disturbance signal is adapted in the feedback path (Francis and Wonham 1975). Such a reduplicated model of the disturbance is called “internal model.” It is now well recognized that forward and inverse internal models (models of the external

environment and its inverse) are widespread in many types of sensorimotor integration in the mammalian brain (Davidson and Wolpert 2005; Tin and Poon 2005).

The optimal solution (Eq. 6) suggests that the respiratory controller may be tracking an apparent metabolic CO_2 load $\dot{V}_{CO_2}/(1 - V_D/V_T)$ instead of the actual metabolic CO_2 load $\dot{V}_{CO_2}$, perhaps through continuous algorithmic identification of the causal relationship of the controller output and resultant chemical–mechanical afferent feedbacks. The projected estimate of this apparent metabolic CO_2 load may take the form of some controller drive signals (indirect adaptive control) or modifiable gain parameters (direct adaptive control), like in engineering adaptive control theory (Fig. 4). Either way, the “exercise stimulus” may amount to some “mental percept” signal emergent from optimal sensorimotor integration rather than an explicit feedforward signal to the controller. Similar internal model sensorimotor integration architecture may also underlie the optimal adaptation of the respiratory pattern to changes in ventilatory mechanical loads.

Hebbian Feedback Covariance Learning and Direct Internal Model Control

Hebbian synaptic plasticity was first postulated by D.O. Hebb over 50 years ago as a mechanism of learning and memory (Hebb 1949). In its original form, Hebb suggested that a synaptic connection can be strengthened if pre- and postsynaptic activities coincided during a short time interval. To circumvent limitations to the classical Hebbian model such as instability and saturation and the lack of reinforcement feedback dynamics in the learning mechanism, Young and Poon (1998) have introduced a Hebbian feedback covariance adaptive control algorithm as a novel paradigm for direct internal model adaptation and reinforcement learning (operant or instrumental conditioning). Unlike classical adaptive control laws which operate deterministically, the feedback covariance adaptive control law is driven by the intrinsic fluctuations of the control signal (such fluctuations are ubiquitous in physiological signals) and resultant covariation of the feedback signal that is

Control of Breathing, Integration of Adaptive Reflexes, Fig. 4 Hypothetical internal model structures for self-tuning adaptive control of respiration. (a) In indirect adaptive control, the metabolic level is continuously estimated by the controller based on an internal model of the causal relationship between the respiratory motor output and chemical feedback. The resultant neuronal estimate provides an indirect “feedforward” signal to the feedback

controller (with fixed gain W) to generate the ventilatory drive. (b) In direct adaptive control, the estimate is directly incorporated in the controller as a variable feedback gain. (c) Two-tier respiratory control system structure with (central and peripheral) chemoreceptor afferent feedback driving an adaptive ventilatory controller and vagal volume-related feedback driving an adaptive central pattern generator signals (Adapted from Poon et al. (2007))

routed back to the controller through the plant dynamics. In its simplest form, the controller gain, w , that determines the optimal input–output relationship is computed by correlating the corresponding intrinsic fluctuations of the control (efferent) signal u and feedback (afferent) signal y :

$$\frac{dw}{dt} = k(\delta y \cdot \delta u) \quad (9)$$

where k is the adaptation constant and δu and δy are the temporal variations of the afferent and efferent signals, respectively, about their corresponding mean values. The adaptation law states that the controller gain (or synaptic weight),

w , will be potentiated if δu and δy are positively correlated and will be weakened otherwise. The parameter w thus encodes an inverse internal model that may track any disturbances in the plant dynamics, such as changes in the metabolic $\dot{V}_{CO_2}$ in the chemical plant of the respiratory system. Young and Poon have shown that, with suitable modifications of the adaptation rule (Eq. 9) to account for the dynamics and delays in the feedback loop, this feedback covariance-based internal model paradigm allows robust direct adaptive control of a general class of linear and nonlinear dynamical systems with stability and convergence guaranteed by Lyapunov theory.

In summary, multiple lines of evidence have strongly suggested that mammalian respiratory control possesses rich adaptive signal processing capabilities in the form of both nonassociative learning and associative learning, which have been ignored in the traditional Sherringtonian framework. New paradigms of adaptive respiratory control will potentially open up new opportunities for more in-depth understanding of homeostatic regulation and sensorimotor control in general.

Control of Locomotion and Scratching in Turtles

Ari Berkowitz

Department of Biology, Cellular and Behavioral Neurobiology Graduate Program, University of Oklahoma, Norman, OK, USA

Definition

The spinal cord contains central pattern generators, which are networks of neurons that can generate coordinated patterns of activity in motor neurons (motor patterns) in the absence of sensory feedback. The turtle spinal cord contains central pattern generators for several kinds of limb movements and is convenient to study physiologically because turtles, being diving animals, have evolved mechanisms to keep tissue healthy under low-oxygen (hypoxic) conditions. Turtle locomotion includes swimming and stepping. Spinal cord central pattern generators have been demonstrated in turtles for forward swimming and

for three forms of scratching, a rhythmic behavior in which the same-side (ipsilateral) hind limb repeatedly rubs against a specific location on the body surface that has been irritated or tickled. Stimulation in a transition zone, at the border of the receptive fields for two forms of scratching, or simultaneous two-site stimulation for two forms of scratching, or for one form of scratching plus forward swimming, can evoke motor pattern blends. Blends may be switches, in which consecutive cycles alternate between two different motor patterns, or hybrids, in which each cycle exhibits characteristics of both motor patterns. The ability of the turtle spinal cord to produce blends suggests that the corresponding central pattern generators are partly shared or that there are strong interactions between components of each. The spinal cord on the opposite (contralateral) side to the scratching limb contributes to generating scratching motor patterns, specifically to the hip-extensor phase of scratching; this circuitry may be part of a bilateral network that contributes to flexor-extensor and left-right coordination for both swimming and scratching. Many spinal interneurons, which are neurons contained entirely within the spinal cord, are multifunctional, meaning that they generate action potentials rhythmically during forward swimming and all three forms of scratching, often bilaterally, and are often activated during limb withdrawal (flexion reflex) as well. Multifunctional interneurons may be components of multiple central pattern generators. Other spinal interneurons, however, are behaviorally specialized: scratching-specialized neurons and flexion reflex-selective neurons are not active, and often are inhibited, during other kinds of motor patterns, and may play a special role in selecting or generating one type of motor pattern.

Detailed Description

Why Study Locomotion and Scratching in Turtles?

Turtles have been used as a model system to study the control of locomotion and scratching in vertebrates since the 1970s. One major reason for their

use is that turtles, being diving animals, have evolved cellular and molecular mechanisms to maintain tissue health under conditions of reduced oxygen (hypoxia) (Lutz and Milton 2004). Such conditions often occur during physiological experiments on reduced or *in vitro* animal preparations, which are often required to study neuronal mechanisms. Thus, researchers are often able to acquire useful physiological data from healthy turtle tissue for about three times as long as they could from comparable mammalian tissue (Hounsgaard and Nicholson 1990).

It is also relatively easy to evoke both locomotion and scratching in turtles, even in reduced preparations and without using exogenous drugs (Stein 2005). The forms of locomotion that have been studied behaviorally include forward swimming, backward swimming (or backpaddling), and forward stepping. Of these, brainstem and spinal cord mechanisms have been studied for forward swimming.

There Are Three Forms of Turtle Scratching

In addition, there are three forms of scratching performed by each hind limb in response to irritation or tickling of the skin or shell (which has sensory innervation). In each form of scratching, the hind limb rubs against a distinct region of the body surface (Fig. 1). A different part of the hind limb and a different knee-hip synergy are used in each form, to target the different regions of the body surface (Mortin et al. 1985). The different synergies required to reach each region are analogous to the different ways humans use to scratch the upper and lower back. In both cases, biomechanical constraints necessitate the use of different limb muscle synergies. Also in both cases, there is a narrow transition zone at the borders of the receptive fields for different forms of scratching. An irritating stimulus within a transition zone can evoke either of the two forms of scratching or sometimes a blend of the two forms. Blends can be switches, in which the limb changes forms on a cycle-by-cycle basis, or hybrids, in which each cycle includes elements of the two

forms. Both switches and hybrids can result in successful rubbing. The receptive fields for rostral and pocket scratching are innervated by contiguous spinal cord segments (i.e., their dermatomes are adjacent and partly overlapping) (Mortin and Stein 1990). The spinal cord segments that provide sensory innervation of the caudal scratch receptive field, however, are more caudal and are not contiguous with the segment innervating the pocket scratch receptive field, being separated by segments that provide sensory innervation of the hind limb instead.

The Turtle Spinal Cord Contains Central Pattern Generators for Swimming and Scratching

The turtle spinal cord can produce the different forms of locomotion and scratching even when all input from the brain is removed. Forward swimming movements of the opposite hind limb can be evoked by electrical stimulation in a region of the spinal cord white matter (the lateral funiculus) in post-cervical spinal cord segments (Lennard and Stein 1977). This stimulation is thought to generate action potentials in the descending axons of reticulospinal neurons (which have been cut off from their cell bodies). Selective lesion of the white matter in this region reduces or eliminates voluntary swimming in otherwise intact turtles.

It has been found in limbed vertebrates generally that locomotion and scratching can be produced without the brain. Moreover, vertebrates without limbs can produce axial locomotion without the brain. Insects can also produce locomotion and scratching without the brain (via the thoracic ganglia). Thus, there is a remarkable conservation of the capacity to produce these rhythmic movements using the central nervous system below the level of the brain. In turtles, at least, the spinal cord is also able to generate blends of two forms of scratching appropriately during stimulation of a transition zone or during simultaneous stimulation of sites in two scratch receptive fields (Mortin et al. 1985; Stein et al. 1986). Blends between swimming and scratching have also been seen (Earhart and Stein 2000). Thus,

Control of Locomotion and Scratching in Turtles, Fig. 1 Schematic illustration of the turtle spinal cord preparation and the forward swimming, scratching, and

limb withdrawal (flexion reflex) motor patterns it generates with different kinds of mechanical or electrical stimulation

coordinated hind limb movement blends can be produced without the brain.

The several forms of swimming and scratching each involve rhythmic contractions of the same hind limb muscles (Lennard and Stein 1977; Robertson et al. 1985). Nonetheless, they can be distinguished from one another based on a set of criteria that involve the amplitudes and timing (i.e., phasing) of muscle contractions. During scratching, knee extension is the major determinant of force generated by the limb against the body surface. A burst of knee-extensor muscle activity occurs during the latter portion of each hip-flexor burst in rostral scratching, during each hip-extensor burst in pocket scratching, and toward the end of the hip-extensor burst and the start of the next flexor burst in caudal scratching. Forward swimming shows a similar knee-hip synergy to rostral scratching, but the knee-extensor and hip-flexor bursts are weaker and briefer, and the hip-extensor bursts are stronger and longer, in

forward swimming as compared to rostral scratching. When forward swim-evoking and rostral scratch-evoking stimuli are delivered simultaneously, the animal produces an adaptive blend of the two (a hybrid), in which the amplitude of hip extension is similar to forward swimming and the amplitudes of knee extension and hip flexion are similar to rostral scratching. The single criterion of the timing of the knee-extensor burst within the hip cycle reliably distinguishes rostral scratching from pocket scratching or caudal scratching, but does not reliably distinguish pocket scratching from caudal scratching or rostral scratching from forward swimming.

The turtle spinal cord can generate the basic patterns of motor neuron activity (i.e., motor patterns) that underlie forward swimming and the three forms of scratching even without movement-related sensory feedback from the limbs (Robertson et al. 1985; Juranek and Currie 2000; Fig. 1). This can be demonstrated by cutting

all of the dorsal roots that carry sensory input from the limbs to the spinal cord, but it is usually demonstrated by chemically blocking acetylcholine receptors at neuromuscular junctions systemically (i.e., the animal is immobilized). The same kind of electrical stimulation in the lateral funiculus that evokes swimming movements in the moving animal evokes forward swimming motor patterns in the immobilized animal. The same kind of mechanical stimulation of the shell or skin that evokes scratching movements in the moving animal evokes each form of scratching motor pattern in the immobilized animal. The patterns of electrical activity in motor nerves that innervate particular hind limb muscles are essentially identical in immobilized animals to the patterns of electrical activity in those muscles during actual swimming and scratching movements. Thus, the spinal cord contains central pattern generators for forward swimming and each form of scratching.

The spinal cord contains sufficient neural circuitry not only to generate the motor patterns for forward swimming and each form of scratching but also to generate adaptive blends of two such motor patterns (Robertson et al. 1985; Stein et al. 1986; Juranek and Currie 2000). Stimulation in a scratch transition zone (rostral pocket or pocket caudal) or two-site stimulation (e.g., rostral + caudal) can evoke appropriate blends of two forms of scratching motor patterns in the immobilized preparation, including both switches and hybrids (Robertson et al. 1985; Stein et al. 1986). Blends between forward swimming and a form of scratching have also been described in the immobilized preparation (Juranek and Currie 2000). Thus, the capacity to produce pure-form locomotion and scratching, as well as coordinated and adaptive blends, is programmed into the spinal cord, in turtles at least.

Several features of scratching motor patterns are consistent with the unit-burst generator hypothesis of Sten Grillner (Grillner 1981) that each joint is controlled by a pair of rhythmogenic modules and inconsistent with the “half-center” hypothesis originally proposed by T. Graham Brown (Brown 1911), at least in its simplest form, which requires mutual inhibition between

flexor and extensor units to generate a rhythm (Stein 2008). A normally occurring variation in rostral scratching (and sometimes other forms of scratching) is missing the hip-extensor phase (i.e., missing both the hip-extensor bursts and the quiescent periods between successive hip-flexor bursts). This is called hip-extensor deletion scratching. Hip-flexor motor neurons continue to burst rhythmically during hip-extensor deletion scratching. This finding suggests that a hip-flexor rhythm can occur in the absence of a hip-extensor rhythm, in contrast to the half-center hypothesis. Knee-extensor bursts can occur normally and can alternate with knee-flexor bursts during hip-extensor deletion rostral scratching, which suggests that the turtle spinal cord contains sufficient neural circuitry to generate rhythmic activity in knee-extensor motor neurons without rhythmic activity in hip-extensor motor neurons (Stein and Daniels-McQueen 2004). This finding is inconsistent with a simple half-center hypothesis in which all limb extensor motor neurons (i.e., both hip and knee) are controlled together. The existence of different knee-hip synergies for the different forms of scratching is also inconsistent with such a simple half-center hypothesis.

The capacity to produce rhythmic, hind limb motor patterns is distributed across several segments of the spinal cord, including all five segments of the hind limb enlargement and the spinal cord segments just rostral to the enlargement (Mortin and Stein 1989). Nonetheless, the more rostral segments of the enlargement and the immediately pre-enlargement segments are more important for generating these rhythms than the caudal enlargement segments are. Spinal cord segments still further caudal are not necessary to generate these rhythmic motor patterns. Similar conclusions have been reached for chick embryo rhythmic activity (Ho and O'Donovan 1993), rodent locomotor-like activity (Cazalets et al. 1995; Kjaerulff and Kiehn 1996; Cowley and Schmidt 1997), and cat scratching motor patterns (Berkinblit et al. 1978; Deliagina et al. 1983). Thus, there appears to be a conserved rostral weighting of spinal cord central pattern generation across limbed vertebrates. The importance of the rostral part of the hind limb enlargement for motor

pattern generation is not directly related to the locations of motor neurons; hip-flexor and knee-extensor motor neurons are located in the rostral segments of the enlargement, but hip-extensor motor neurons are located in caudal segments of the enlargement, in turtles (Ruigrok and Crowe 1984) as in mammals (Romanes 1964).

It is possible to evoke some of these hind limb motor patterns *in vitro*. The turtle spinal cord with a region of the rostral shell still attached to it via peripheral nerves can be used to evoke rostral scratching motor patterns using natural stimulation of the shell *in vitro* (Keifer and Stein 1983; Alaburda and Hounsgaard 2003). Also, the turtle spinal cord with a particular cutaneous nerve (the ventral posterior pocket) attached can be used to evoke pocket scratching motor patterns via nerve electrical stimulation *in vitro* (Currie and Lee 1996).

Neurotransmitters and Ion Channels

Glutamate and glycine have been shown to play important roles in scratching motor patterns. Bath application of glutamate agonists (NMDA and AMPA) to the turtle spinal cord *in vivo* and *in vitro* can evoke rhythmic activity of motor nerves that is similar to scratching motor patterns (Currie 1999). Scratch sensory stimulation can reset these rhythms, indicating interaction, at least, between the networks that produce glutamatergic rhythms and those that produce scratching. Blocking NMDA receptors reduces the rate of the scratching rhythm and the temporal summation of sensory inputs that evoke scratching motor patterns for rostral scratching *in vivo* (Currie and Stein 1992) and for pocket scratching *in vitro* (Currie and Lee 1996). Some individual spinal cord interneurons (i.e., neurons contained entirely within the central nervous system) are similarly active for many seconds following a single scratch stimulus and may contribute to temporal summation during scratching (Currie and Stein 1990). Such interneurons can also have their multisecond activity reduced by blocking NMDA receptors (Currie and Stein 1992). Glycine, on the other hand, slows rostral

scratching motor patterns and blocking glycine receptors speeds them up (Currie and Lee 1997).

Motor Neurons During Locomotion and Scratching

Hind limb motor neurons may contribute actively to the amplitude and perhaps the timing of turtle scratching and swimming rhythms. Motor neurons receive alternating but temporally overlapping excitatory, depolarizing inputs and inhibitory, chloride-dependent, hyperpolarizing inputs during scratching motor patterns *in vivo* (Robertson and Stein 1988; Stein 2010). Intrinsic properties of motor neurons can be studied in more detail in slice preparations, which can be made especially thick for turtle spinal cord, because of its unusual resistance to hypoxia (Hounsgaard and Nicholson 1990). Some motor neuron dendrites can produce calcium-dependent action potentials (Hounsgaard and Mintz 1988). Motor neurons also show bistability or plateau potentials, primarily in the dendrites, meaning that their membrane potentials are stable at two different levels, one of which (the resting potential) is below action potential threshold and the other of which is above it (Hounsgaard and Mintz 1988). This bistability might contribute to the strength and duration of each motor neuron burst during scratching.

The bistability depends on l-type (persistent) voltage-dependent calcium channels, especially CaV1.3 channels (Hounsgaard and Mintz 1988; Alaburda and Hounsgaard 2003; Simon et al. 2003), as well as calcium release from the endoplasmic reticulum via ryanodine receptors (Mejia-Gervacio et al. 2004). There are also calcium-dependent nonspecific cation channels in turtle motor neurons, but they are not required for plateau potentials (Perrier and Hounsgaard 1999). The plateau potentials can be affected by a number of neuromodulators (Delgado-Lezama et al. 1997; Svirskis and Hounsgaard 1998). The plateau potentials are augmented by serotonin (especially via 5-HT₂-type receptors) (Hounsgaard and Kiehn 1989; Perrier and Hounsgaard 2003), group I metabotropic

glutamate receptors, and muscarinic acetylcholine receptors. Plateau potentials are generally increased by neuromodulators that close potassium channels (Hounsgaard and Mintz 1988). A compartmental model of turtle motor neurons also suggests that neuromodulators close potassium channels and that serotonin has multiple effects via different types of ion channels that are differentially distributed in the cell (Booth et al. 1997). In slice preparations, motor neurons can produce oscillations in the presence of the glutamate agonist NMDA even when all action potentials are blocked (by tetrodotoxin) (Guertin and Hounsgaard 1998). These NMDA-dependent motor neuron oscillations disappear if l-type calcium channels are blocked.

Although intrinsic properties of motor neurons may contribute to shaping their bursts during scratching (Alaburda and Hounsgaard 2003), the synaptic input to motor neurons is so strong during rostral scratching motor patterns *in vitro* that it likely overwhelms and suppresses motor neuron intrinsic properties like plateau potentials, which may consequently play a relatively minor role during scratching (Alaburda et al. 2005).

Spinal Interneurons Involved in Locomotion and Scratching

Much is still unknown about the spinal cord interneurons and pathways that mediate locomotion and scratching in turtles and in limbed vertebrates generally. However, some things are known (Berkowitz 2010). Turtles have been particularly useful for studying the extent to which networks of interneurons that generate forward swimming and the three forms of scratching in each hind limb are shared versus separate. It is known that many spinal cord interneurons are rhythmically activated during forward swimming and all three forms of scratching (Berkowitz and Stein 1994a, b; Berkowitz 2001a, b, 2002). These multifunctional interneurons are found throughout the hind limb enlargement spinal cord, as well as in spinal cord segments rostral to the hind limb enlargement (Berkowitz 2001a, b). In the transverse plane, these interneurons are scattered

through the ventral part of the dorsal horn, the intermediate zone, and the dorsal part of the ventral horn. At least some of these interneurons have axon projections that terminate in the ventral horn (Berkowitz 2005, 2008; Berkowitz et al. 2006), consistent with their contributing to motor output during all of these motor patterns, although their synaptic targets are not yet known. Thus, there is a strong likelihood that the networks generating these distinct forms of rhythmic hind limb movement partly overlap in turtles.

Multifunctional and Specialized Spinal Interneurons

Most scratch-activated interneurons are activated during stimulation of the body surface for all three forms of ipsilateral scratching and often contralateral scratching as well (Berkowitz 2001a, b). Nonetheless, most such interneurons are most strongly activated during stimulation of one particular region of the body surface and are progressively less strongly activated during stimulation of sites progressively further away from this preferred region. Thus, the activity of these neurons does not precisely indicate which site has been stimulated. Instead, each is broadly tuned to a region of the body surface. Different scratch-activated interneurons within one animal's spinal cord are broadly tuned to different regions of the body surface. The combination of several such interneurons with different tuning (i.e., population coding) can in principle specify precisely which site has been stimulated and thus which form of scratching should be generated to initiate contact with that site (Berkowitz 2009). If, indeed, the turtle spinal cord uses a large population of broadly tuned interneurons to code stimulus locations and corresponding movement directions, this would be similar to population coding in many animals and for many behaviors, from leech local bending to primate arm reaching (Briggman and Kristan 2008).

Nonetheless, some turtle spinal cord interneurons are behaviorally specialized (Fig. 2; Berkowitz 2010). Some interneurons are rhythmically activated during scratching motor patterns,

Control of Locomotion and Scratching in Turtles, Fig. 2 Schematic Venn diagram illustrating multi-functional and specialized types of spinal interneurons

but are not activated at all or are even inhibited during forward swimming motor patterns (Berkowitz 2002, 2008). In addition, there are interneurons that are strongly activated during limb withdrawal (flexion reflex) motor patterns that are inhibited during forward swimming and each form of scratching motor pattern (Berkowitz 2007). The relative roles and effects of shared versus behaviorally specialized interneurons are not yet understood in turtles. There is also evidence from hatchling tadpoles and larval zebrafish that a combination of shared and behaviorally specialized interneurons contributes to different forms of axial locomotion (Berkowitz et al. 2010). Less is known about the extent to which circuitry is shared in the control of different forms of locomotion and scratching in mammals.

Rhythmic Activity of Spinal Interneurons

Spinal cord interneurons that are activated during swimming and scratching motor patterns tend to be rhythmically active or at least have firing rates that are rhythmically modulated. Most such interneurons tend to fire action potentials (i.e., have a preferred phase) during a particular phase of the hip flexion-extension cycle and tend to maintain this preferred phase across all three forms of scratching and often during forward swimming as well (Berkowitz 2001a, b, 2002). Thus, control of hip movement timing appears to dominate

spinal cord interneuron rhythmic activity. Interneurons that are rhythmically active during the hip-extensor phase of scratching motor patterns are generally quiet during hip-extensor deletions, while interneurons that are rhythmically active during the hip-flexor phase are generally active during hip-extensor deletions, suggesting that there is an entire module of interneurons and motor neurons that is inactive during hip-extensor deletions (Stein and Daniels-McQueen 2002; Stein 2008).

In addition to rhythmic, hip-related interneurons, some interneurons do shift their peak firing within the hip activity cycle between scratching and swimming or between one form of scratching and another (Berkowitz 2001a, b, 2002). Such interneurons could be involved directly in control of other joints, such as the knee or ankle, consistent with the unit-burst generator hypothesis. Rhythmic interneurons have been studied that generate bursts of action potentials correlated with knee-extensor or knee-flexor motor neuron activities (Stein and Daniels-McQueen 2003). Some spinal cord ventral horn and dorsal horn interneurons also show the same kind of bistability as seen in motor neurons (Hounsgaard and Kjaerulff 1992; Russo and Hounsgaard 1994, 1996).

Among the spinal cord interneurons that are rhythmically activated during forward swimming and all three forms of scratching is a class of interneurons called transverse interneurons, or T neurons, that can be delineated by their somato-dendritic morphologies (Berkowitz et al. 2006). These interneurons have dendrites that extend far dorsoventrally and mediolaterally (i.e., in the transverse plane) but are short rostrocaudally; they also tend to have a soma that is longer mediolaterally than rostrocaudally. T neurons tend to be very rhythmically active during both swimming and scratching (Berkowitz 2008). They also tend to have higher peak firing rates during scratching, larger membrane potential oscillations during scratching, and briefer afterhyperpolarizations following action potentials than other scratch-activated interneurons (Berkowitz et al. 2006). T neurons are also typically activated during ipsilateral limb

withdrawal. At least some T neurons have axon terminals in the ventral horn in the hind limb enlargement. Thus, T neurons are good candidates to play an important role in motor control for a wide range of limb movements.

A hypothetical architecture has been proposed that could in principle generate the correct knee-hip synergies for rostral scratching and pocket scratching using only broadly tuned interneurons that preferentially fire action potentials in a particular phase of the hip cycle (Fig. 3; Berkowitz 2001a, b). Each such interneuron would project to both a knee motor neuron pool and a hip motor neuron pool. According to this hypothesis, interneurons that are broadly tuned to a rostral scratch region would project to both knee-extensor and hip-flexor interneurons, while interneurons that are broadly tuned to a pocket scratch region would project to both knee-extensor and hip-extensor motor neurons. The knee-hip synergy would then be determined in motor neurons, especially knee-extensor motor neurons, that integrate excitatory and inhibitory inputs with different but overlapping time courses. There is evidence from intracellular recordings of knee-extensor motor neurons that they do receive excitatory and inhibitory postsynaptic potentials that overlap in time during rostral and pocket scratching motor patterns (Robertson and Stein 1988).

Control of Locomotion and Scratching in Turtles, Fig. 3 Hypothetical architecture to account for how broadly tuned spinal interneurons could generate the correct knee-hip synergies for rostral and pocket scratching. Each interneuron would project to two motor neuron pools (directly or indirectly), with differently tuned interneurons having different dual projections. Knee-extensor motor neurons would integrate overlapping excitatory and inhibitory inputs from differently tuned interneurons, thus determining the timing of knee-extensor bursts within the hip cycle. Whichever group of interneurons was more active would determine the knee-hip synergy

Dual Stimulation

The large set of spinal interneurons that are rhythmically activated during both swimming and scratching motor patterns suggests that the central pattern generators for swimming and scratching have common members or at least strong interactions between them. Another way of addressing this question is to deliver two stimuli simultaneously that each individually evokes one of the two motor patterns. If the sets of interneurons that generate the two motor patterns are entirely separate (i.e., the central pattern generators are separate), then simultaneous stimulation should generate a superposition of the two rhythms within motor neurons. If many of the central pattern generator interneurons are shared (or have strong interactions between them, which might be equivalent), however, then one stimulus might modify the motor pattern produced by the other stimulus in a coordinated manner (Berkowitz and Hao 2011).

As noted above, simultaneous stimulation of the body surface in regions that evoke two different forms of scratching can evoke coordinated and adaptive blends of the two (Robertson et al. 1985; Stein et al. 1986). In addition, brief forward swim stimulation can interrupt and reset the rostral scratching rhythm and vice versa (Juranek and Currie 2000). (Also, brief stimulation to evoke a limb withdrawal or flexion reflex motor pattern can reset the scratching rhythm (Currie and Stein 1989).) Finally, prolonged simultaneous forward swim stimulation and scratch stimulation (for all three forms of scratching) can generate swim-scratch blends, generate a swim rhythm when the swim stimulation alone is insufficient, generate a pure-form swim rhythm with a rhythm frequency greater than that evoked by either stimulation alone, and sometimes disrupt one phase of the rhythm or disrupt rhythm generation entirely (Hao et al. 2011). These physiological findings suggest that there are either substantial common elements to the swimming and scratching central pattern generators or strong interactions between the generators.

Computer simulations were also generated of simplified models of caudal scratch and forward

swim networks that were (1) entirely separate, (2) separate but interacting, and (3) shared central pattern generators (Hao et al. 2011). The results of these simulations suggested that shared or strongly interacting central pattern generators can account for the physiological findings but completely separate central pattern generators cannot. The strongly interacting simulated networks and especially the shared simulated network replicated the physiological findings of increased rhythm frequency under dual stimulation and summation of a subthreshold swim stimulus with a suprathreshold scratch stimulus to generate a suprathreshold swim. The success of these models depended on neurons switching their phase in the swim rhythm via escape from inhibition.

Left-Right Hind Limb Coordination

Coordination between the left and right hind limbs also can be generated by the spinal cord. In intact turtles performing forward swimming spontaneously, forward swimming involves alternating (i.e., out-of-phase) coordination between left and right hind limb movements (Field and Stein 1997). Surprisingly, such coordination continues after a cut along the midline of the spinal cord (separating the left and right sides) throughout the hind limb enlargement and the immediately pre-enlargement segments (Samara and Currie 2007). This shows that commissural pathways in more rostral regions (including the forelimb enlargement) are sufficient to produce left-right hind limb alternation.

Scratching, however, is essentially a unilateral behavior; the ipsilateral hind limb rhythmically rubs against the stimulated site, while the contralateral hind limb remains relatively still (Mortin et al. 1985). A close look at the activity of contralateral motor neurons during unilateral scratch stimulation, however, has revealed that they typically are weakly but rhythmically activated in alternation with their ipsilateral counterparts during unilateral scratching (Currie and Stein 1989). It is not clear if this contralateral motor neuron activation is adaptive during scratching; it might

be an epiphenomenon due to activation of networks that are shared between swimming and scratching. In addition, bilateral scratch stimulation and unilateral scratch stimulation near the midline (e.g., near the tail) can evoke bilaterally coordinated scratching movements of the left and right hind limbs (Field and Stein 1997), which might rely on the same spinal cord circuitry that underlies left-right coordination during bilateral swimming. Bilaterally evoked scratching usually involves alternation between the two hind limbs, but can involve synchronized (in-phase) movements, especially for caudal scratch stimulation near the tail. On occasion, the left and right hind limbs display 2:1 coordination, in which one limb moves through two cycles in exactly the time that the other limb moves through one cycle (Stein and McCullough 1998).

Many spinal cord interneurons that are rhythmically activated during ipsilateral scratching motor patterns are also robustly and rhythmically activated during contralateral scratching motor patterns (Berkowitz and Stein 1994a, b; Berkowitz 2001a, b). Such interneurons might be components of networks that produce the coordinated activity in contralateral motor neurons during scratching and potentially during swimming as well. Some such interneurons are rhythmically active in the same phase of the ipsilateral hip-flexor rhythm no matter which side is stimulated, while other such interneurons switch to the opposite phase when the opposite side of the body is stimulated. Collectively, such interneurons could mediate the in-phase and out-of-phase left-right limb coordination that has been observed during scratching and locomotion.

But does the contralateral spinal cord actually play a role in generating unilateral scratching motor patterns? Surprisingly, the answer is yes, as shown by experiments in which the spinal cord on one side was removed, throughout the hind limb enlargement (Stein et al. 1995). Stimulation of the body surface on the intact side evoked a strong rostral scratching rhythm on that side that was consistently missing the hip-extensor phase (i.e., hip-extensor deletion rostral scratching). Stimulation of the body surface on the lesioned side (but rostral to the lesion) evoked a

hip-extensor rhythm alone on the intact side. Both of these findings suggest that the contralateral spinal cord contributes a specific component to the scratching motor pattern, namely, the hip-extensor phase.

In other experiments, a hemisection (i.e., a spinal cord transection limited to one side, e.g., the left) was used to eliminate stimulation of the left hind limb enlargement via ipsilateral descending axons on the left and contralateral descending axons from the right (Stein et al. 1998). In this case, stimulation of the body surface on the intact right side (rostral to the hemisection) evoked hip-extensor deletion rostral scratching. Stimulation of the body surface on the left side (rostral to the hemisection) in combination with the stimulation on the right side evoked a normal rostral scratching rhythm (including the hip-extensor phase), i.e., the rostral scratch motor pattern was “reconstructed” by this two-site stimulation. This finding suggests that descending, crossed axons activate interneurons that produce the hip-extensor phase of scratching and that these interneurons are coordinated with interneurons that are activated through unilateral pathways. In addition, crossed pathways in pre-enlargement segments are sufficient to create the left-right alternation during bilateral rostral scratch stimulation.

All of these findings, in combination with the single-neuron recordings of interneurons that are bilaterally activated during scratching, suggest that there is a bilateral set of interneurons that each contribute to both left and right hind limb scratching (Stein et al. 1995). This set of shared neurons might contribute to bilateral coordination for both scratching and swimming. Surprisingly, though, one side (left or right) of the hind limb enlargement is sufficient to produce rhythmic hip-flexor, hip-extensor, and knee-extensor muscle activities with appropriate phasing during forward swimming movements evoked by electrical stimulation of the contralateral lateral funiculus (in the rostral spinal cord), though cycle frequency and muscle burst amplitude are lower than otherwise. Thus, the contralateral hind limb enlargement spinal cord may actually play a more important role in generating unilateral scratching than in generating unilateral swimming.

Crossed glycinergic inhibition appears to contribute to bilateral coordination during scratching, as coordination is more variable when glycine receptors are blocked (Currie and Lee 1997). Glycinergic inhibition cannot be necessary for coordination during scratching, however, as left-right coordination can continue under glycine receptor blockade.

Coordinate Transformations, Role of Spinal Circuitry in

Yifat Prut

Department of Medical Neurobiology, Hadassah Medical School, The Hebrew University, Jerusalem, Israel

Synonyms

[Descending control of spinal circuitry in voluntary movements](#); [Role of descending pathways in extrinsic to intrinsic coordinate transformation](#); [Spinal control of voluntary movements](#)

Definition

The process through which a motor target in the external environment is translated into a body-centered coordinate system is called coordinate

transformation. In the motor system, this translation is often referred to as the transformation of an externally defined (e.g., in a retinotopic coordinate frame) target into a muscle-based (or intrinsically defined) motor command. Multiple cortical areas are known to be involved in this process. Many of these areas, including pre- and post-central sites, project downstream to activate directly and indirectly spinal neurons. The interaction of this extensive system of descending pathways with spinal circuitry may further adjust motor commands before they reach target muscles in a final processing step of coordinate transformation.

Detailed Description

When making a movement directed toward a target in the world around us, the nervous system is faced with a computationally difficult task. The target which is initially defined in a retinotopic coordinate system must be translated into a detailed body-centered motor command that specifies the required spatiotemporal activation profile of all muscles (Shadmehr and Wise 2005). This computation is completed on the fly and in an unconscious manner. It is generally assumed that this process is the outcome of cortical processing in which multimodal sensory information is integrated and converted into appropriate motor commands (Sabes 2011). However, there are several reasons why segmental interneurons (INs) could also contribute to the process of coordinate transformation. First, the segmental network of interneurons is situated between the motor cortical network and corresponding motoneurons (MNs) such that most of the cortical information sent to MNs is relayed via INs (Porter and Lemon 1993). Second, multiple cortical areas transmit information to spinal neurons, including the motor and premotor areas, which could provide INs with diverse information that contains both high- and low-level features of the motor command (Dum and Strick 2002). Some descending output emerges from sensory areas of the parietal lobe, which in itself could provide segmental neurons with sensory-related information (Kuypers 1987;

Toyoshima and Sakai 1982). Other sources of descending input such as the vestibulospinal and rubrospinal pathways may provide further state variables related to posture, balance, etc. that could be relevant to the spinal processing of coordinate transformation (Baldissera et al. 1981). In addition to these sources of processed information, spinal neurons integrate proprioceptive inputs which are relayed via a rich afferent system. Finally, neighboring INs have been shown to engage with local interactions (Jankowska 1992) which can modify converging inputs before finally affecting MNs.

This entry reviews the mounting evidence that spinal neurons provide the final processing step for completing the coordinate transformation in the motor system. It further develops the concept that in addition to the spatial coordinate system, spinal processing also modifies the temporal pattern of descending commands to match it with the required pattern of muscle activation. Finally, the possible implications of this organizational scheme in which motor commands are finalized downstream to M1 are discussed in terms of current research in the field of motor control.

Activity of Spinal Interneurons During Voluntary Movement

There is abundant work on the organization of segmental circuitry in reduced preparations (i.e., cats, rodents, and in some cases monkeys). These studies have mostly concentrated on the input to these neurons from local, peripheral, and/or descending sources. Nonetheless, understanding the functional contribution of spinal neurons to any type of motor behavior requires recording single cell properties and cell-to-cell interactions during task performance, since these characteristics considerably affect the input-to-output transformation of any network. The ability to induce fictive locomotion in reduced preparations (e.g., isolated spinal cord) has led to extensive study of interneuron (IN) activity in these conditions. However, these studies concentrate on spinal network activity rather than its control by descending corticospinal pathways, which

however is the fundamental component of voluntary motor control. Early studies of cervical spinal neurons during normal motor behavior of primates (Fetz et al. 1999) showed that there is both directional and torque tuning of these neurons as well as connectivity with muscles. The connections of INs with muscles were biased toward flexor muscles unlike the generally even corticomuscular connectivity found for motor cortical neurons that have a functional link with flexors and extensors muscles (Fetz 1992). Later studies revealed that spinal neurons are not only active during motor action but modify their rate when preparing for movement during an instructed delay period (Prut and Fetz 1999). This finding demonstrated that spinal INs are not merely related to motor execution but also receive information (which can be excitatory or inhibitory) during motor preparation. Via ascending pathways, this spinal activation can back-modify cortical activity during the pre-movement delay period when coordinate transformation apparently takes place. Further investigation of spinal activity during a two-dimensional wrist task (Harel et al. 2008) revealed that the tuning properties (such as the width and height of tuning curves) were very similar for both motor cortical and spinal neurons but that the distribution of preferred directions (PDs) tended to be more biased across spinal neurons as compared to the uniform distribution of cortical PDs (Georgopoulos et al. 1986). This result provided a first indication that spinal circuitry process arriving input in order to match it to working muscles. Nonetheless, the response properties of spinal neurons have not been found to be dramatically different from those found for motor cortical cells. Thus a general conclusion that can be drawn from studies of the task-related activity of spinal neurons is that these neurons express a rich spectrum of firing properties that are related to different aspects of the task including both motor and non-motor properties.

Some differences have been reported in the firing properties of spinal and cortical neurons. First, spinal neurons generally exhibit higher firing rates than cortical neurons. However, this enhanced firing is more regular (in terms of the

inter-spike interval) and less correlated among neighboring interneurons than that of cortical neurons. Specifically, the spinal noise correlation was found to be independent of the signal correlation recorded for these cells (Averbeck and Lee 2004). Hence neighboring neurons with similar response properties do not express any tendency for rate co-modulation on a trial-to-trial basis. Thus spinal neurons may “amplify” a cortical command and provide a more rigorous drive to working muscles while at the same time spinal circuitry can eliminate any redundancy in the command which may exist at the motor cortical level (Lee et al. 1998).

Integration of Sensorimotor Information in the Primary Motor Cortex

The next step in understanding the contribution of spinal neurons to coordinate transformation is to characterize the properties of the motor command emitted by the motor cortex. The motor cortex integrates multiple sources of information in various modalities as required for performing some form of sensory-to-motor transformation. Information about higher aspects of motor actions and external targets is relayed to the motor cortex via the premotor areas. Neurons in the primary motor cortex may thus express responses to a large set of environmental cues, as long as they are informative about the action to be made. For example, a general visual cue may produce a very weak response in M1, whereas a similar cue that contains directional information may trigger a robust response in the same cell (Asher et al. 2010). Furthermore, even variables which normally are not expected to be coded for in the motor cortex (such as the color of a cue) may induce a distinguishable response as long as they are relevant to the ensuing movement (Zach et al. 2008). In this respect the motor cortex apparently codes the *motor-relevant* information regardless of its specific modality.

Along with information about the environment and targets, the motor cortex receives somatosensory information from the somatosensory cortex which provides it with details about the state of the

plant. It appears that while visual information can be suppressed at the level of motor cortex based on its relevance to the ensuing action, motor cortical response to somatosensory cues (e.g., unexpected perturbation of the arm) is extensive and robust. This is reasonable since any change in the state of the periphery is important for the motor machinery as regards updating and correcting the planned and/or executed movement. Nonetheless, there is evidence that as soon as a movement has been initiated, some sensory information (i.e., cutaneous information) is attenuated in a way which could potentially serve to enhance the feedforward component of motor control. This implies that at least this component of sensory information is important for planning actions, but not for its online guidance.

In addition to the corticocortical information that is integrated by motor cortical neurons, thalamocortical input relays information from the cerebellum and the basal ganglia. This information appears to be more crucial to action selection and action timing (Hikosaka 1998) and thus may not play a dominant role in coordinate transformation. Hence motor cortical neurons appear to integrate different sources of corticocortical information in a weighted manner which is related to the importance of these sources to motor performance. One operative framework that captures this property of motor cortical activity is the Optimal Feedback Control model which posits that motor cortical activity manipulates and optimizes feedback gains in order to minimize some task-specific cost function (Scott 2004; Todorov and Jordan 2002). However, this theory provides no explicit account of the transformation of coordinates by the system.

The Coordinate Frame of Motor Cortical Information

The end result of motor cortical integration is a motor command to the working muscles. The exact coordinate system within which this motor command is specified is a topic of ongoing debate. The classical view suggested a muscle-based coordinate system (Evarts et al. 1984), whereas

later views posited that cortical neurons operate in an extrinsic-based coordinate frame (Georgopoulos et al. 1986). However, the general consensus today is that motor cortical neurons operate in a system that combines both coordinate systems and thus mostly contains a mixed representation of both target-related and muscle-related information, in a fairly heterogeneous manner across the motor cortex (Kalaska 2009).

Early studies used a behavioral paradigm in which monkeys were trained to perform a center-out wrist task with three different hand postures: pronation, mid-position, and supination (Kakei et al. 2003). The use of a single-joint task that relies on the near-isotropic wrist joint allowed for a systematic exploration of the impact of hand posture on spatial tuning properties of motor cortical neurons (compared to a similar approach that was used in a reaching task; Scott and Kalaska 1997). The authors were able to distinguish between three different coordinate systems: external, muscle-based, and joint-based. They found that the majority of neurons exhibited a small shift in their preferred direction (30° shifts on average when the hand rotated from pronation to supination and the muscle rotated $\sim 75^\circ$). Moreover, recordings in the premotor ventral cortex (PMv) revealed that neurons in this high-level motor cortical site do not change their PD during the task; i.e., their tuning is not affected by hand posture. A study that used the same paradigm in primates during spinal recordings revealed that although the majority of spinal neurons express PD shifts that were similar to muscles, cortical neurons recorded at the same time expressed, on average, a much smaller PD shift. The authors concluded that the transformation from external to internal coordinate frame is completed downstream of M1. More generally, the transformation of the coordinate frame does not take place within a single site; rather, there is a gradual and successive transition of the coordinate system via inter-site interactions.

Theoretical studies have argued that it is impossible to deduce the coordinate frame from PD shifts (Shah et al. 2004) because when shifting postures, neurons modify both their PDs and firing rates (often quantified as a dynamic index

which is the difference in firing range in the two postures over the sum of these ranges). This suggests that in practice it is possible to obtain any type of coordinate system irrespective of the extent of PD shift, since there can be a tradeoff between changes in PD and dynamic indices. Nevertheless, spinal neurons and cortical neurons were shown to exhibit similarly symmetric distribution of dynamic indices but different PD shifts. Thus spinal neurons participate in the process of coordinate transformation by providing the final computational step which includes removing any external-based information (which is non-separable at the cortical level) and thus rotating the PD to fit the exclusively muscle-based frame.

Dynamic Properties of Coordinate Transformation

The concept of coordination transformation is often viewed in a “timeless” manner. In other words, the coordinate system of each neuron is considered to be a fixed property that does not change over time. However, this is not necessarily the case. During a behavioral trial the nervous system collects increasingly more information about task-relevant parameters. In addition, the relevance of external cues and the internal state can change along the trial. For example, at cue onset, the spatial information about the cue (which is often given for a short period of time) is critical for correct task performance, whereas the posture of the hand or other muscle-based parameters is less relevant at this stage. By contrast, at the “go” signal, any plan for movement relies on information about posture and muscle states. Indeed it was shown that the coordinate frame of cortical neurons (which unlike spinal neurons have access to information in different modalities) gradually shifts during motor preparation to execution from an external to an internal mode (Harel et al. 2008). This result is similar in spirit but very different in detail from the mental rotation of the population vector reported by Georgopoulos et al. (1989) where the PV shifted from the cued to the actual movement but remained in an externally

based frame of coordinates. Accordingly, integration of different sources of information (e.g., a postural variable and a directional cue) should be modeled using time-dependent weight variables.

Spinal Targets of Descending Pathways

The possibility that the final step in coordinate transformation takes place at the spinal level does not necessarily imply that spinal interneurons are actively or exclusively involved in this processing stage. The termination pattern of corticospinal pathways is rich and extensive in both human and nonhuman primates. These pathways tend to affect interneurons that are located in the intermediate zone, and thus most of the descending cortical command is first processed at this level, though it is possible that some of the command (e.g., a finger-related command) is relayed directly to MNs. The detailed scheme of termination of this pathway could, in itself, provide a processing link for cortical commands. Any organization scheme that respects one descending parameter but ignores another will preserve the information related to the former but not the latter attribute. For example, if all cortical neurons that contain similar PD terminate onto the same spinal target, the PD information will be preserved at the postsynaptic level. However, if the PD distribution of cortical cells that converge upon the same spinal target is uniformly distributed, the directional information will be averaged out. This by no means implies that the spinal target will not be directionally tuned; simply this tuning will not be driven by cortical commands.

Studies stimulating in the motor cortex while recording in the spinal cord uncovered the CS connectivity pattern in awake behaving primates. These studies revealed a very broad CS connectivity pattern with many cortical sites that affect spinal targets. Furthermore, interacting cortical and spinal neurons express aligned directional-torque tuning at movement onset, whereas unconnected sites have inverse tuning directions. This finding further suggests that although information on directional torque is preserved in the CS system, it is organized in a very broad manner; namely, cortical neurons with vaguely

Coordinate Transformations, Role of Spinal Circuitry in, Fig. 1 A Model of the functional organization of the CS system. (a) Motor cortical neurons integrate information about the motor targets ($x_1, \dots, x_n$) and about the peripheral state ($y_1, \dots, y_m$) with time-varying weight constants ($W_x(t)$ and $W_y(t)$), respectively. This integration occurs at random and the resultant response properties of cortical neurons are heterogeneous (depicted as differences in the shading of cortical neurons). Lateral interactions can further modify the response properties and the coordinate frame of the cortical layer. Cortical neurons are characterized by a time-dependent response pattern that appears as a transient signal. Spinal interneurons integrate

similar tuning will tend to affect a single spinal site. In practice this result is consistent with a nonspecific connectivity pattern so that a heterogeneous population of cortical neurons converges upon spinal circuitry (Fig. 1). This differs from the assumption of a unique population of output motor cortical cells that deliver a muscle-based motor command and are specifically connected with premotor spinal targets.

Role of Spinal Interneurons as a “Neural Integrator”

In the process of translating the cortical command into a signal to drive muscles, the spatial coordinate frame as well as the temporal profile of the task-related activity needs to be adjusted. Cortical neurons have often been shown to code time derivatives of motor parameters (e.g., velocity; Schwartz et al. 1988), yet at the pre-muscle

cortical inputs and produce a motor command which is integrated and rotated into a muscle-based command. At this level the response properties are more uniform than at the cortical level. To the left of each layer, a diagram illustrates the mean response profile of cells. (b) Frequencies of different response patterns for cortical neurons (orange), spinal interneurons (blue), and motoneurons (black). Response pattern was quantified using a phasic-tonic index which approached 1 for phasic cells and 0 for tonic cells. Cortical cells had a broader distribution with a significantly higher mean value (a tendency toward phasic firing), whereas spinal interneurons had a narrower distribution with a lower mean value

level, this information needs to be integrated into the required shape of force profile. The alternative that the intrinsic properties of MNs could by themselves integrate a transient motor command for voluntary action seems unlikely given the short time scales available for this operation (Heckman et al. 2009). We found that when sustained torque is required, motor cortical firing is different from spinal firing in two main ways. First, cortical firing is transient, whereas spinal firing is tonic. Second, cortical neuron firing is less informative than spinal neurons about static variables such as hand posture. Similar properties have been reported for the eye movement system where cerebellar receiving neurons fire in relation to eye acceleration, vestibular neurons fire in diverse relations to eye movement parameters, but the abducens MNs fire in relation to eye position (Joshua et al. 2013). In this system it was suggested that a “soft” feedforward hierarchical network can act as an integrator (Joshua et al.

2013; Miri et al. 2011). Similar events may also take place in the corticospinal system where cortical neurons exhibit fairly diverse firing properties and broadly converge upon spinal neurons; here, the needed integration is already present at the spinal interneuronal level.

Modular Organization Versus Coordinate Transformation

A conceptual, data-based model of the functional organization of the motor system suggests that the motor system is characterized by a modular organization principle (Bizzi et al. 2000, 2008). In this scheme, motor actions are constructed by the spatiotemporal superpositioning of basic modules that can be viewed as elementary building blocks of movements (often referred to as motor primitives). Each module provides an activation of a set of muscles (i.e., a muscle synergy). These modules were first extrapolated from work on spinal stimulations of spinalized frogs and appeared to offer an elegant way to mediate coordinate transformations. In this model, a cortical activation signal (presumably expressed in an external frame of coordinates) activates the necessary set of modules which in turn incorporate the descending command into the ongoing motor state. Although considerable data on motor behavior supported the existence of a robust set of motor synergies, their neural substrate remained unclear. More recently, it was shown that electrical activation of the motor cortex in primates produces motor responses which have the characteristics of motor synergies. This result is consistent with earlier studies that showed that prolonged activation of the motor cortex in primates produces a finite repertoire of movements which mimic natural actions (i.e., defensive gestures, self-feeding, etc.; Graziano and Aflalo 2007). Could these results be interpreted as an indication that the motor primitives in fact reside in the motor cortex? In that case, the translation from external to internal coordinate frame appears less intuitive. For example, we would need to assume that motor cortical neurons

that are part of a single module randomly sample the more externally based variable space, since otherwise the resultant motor activation might be biased. More data are needed to understand in what way the modularly organized system deals with coordinate transformation.

Implications for BMI

In recent years many studies have demonstrated that useful signals can be extracted from motor cortical activity to drive prosthetic devices (Hatsopoulos and Donoghue 2009; Schwartz 2007). These devices range from an on-screen cursor to a humanoid robotic limb with multiple degrees of freedom. The most common approach employed in these studies is to assume a fixed coordinate frame (either extrinsic or intrinsic) of these signals. However, findings have shown that the activity of cortical neurons is affected by the operative context. For example, hand posture induces a consistent bias of PDs across motor cortical neurons, which thus cannot be eliminated by population averaging. Furthermore, trial time systematically affects the PDs of cortical neurons. Finally, it is conceivable that the behavioral context may entail other parameters such as mental states which are difficult to control for but may nevertheless affect the PD of cortical neurons in a consistent manner that cannot be eliminated by averaging. In this respect using motor cortical activity as part of a long-term control signal should be consistently updated with an adaptive algorithm that reweighs the activity of different cells to prevent a gradual deviation between the intended and the reconstructed actions.

Definition

Voluntary movements are typically coordinated in the sense that their components form ordered patterns. This includes the coordination of different spatial components of a movement, the coordination of different limbs, and also the coordination of movement with perceived events. More formally, coordination is characterized by stable relative timing of the movement components. Coordination dynamics is a theoretical approach to understanding how coordination arises which postulates that neural oscillators control the timing of each component. The coupling among such neural oscillators leads to stable relative timing. Mathematical models of coordination dynamics have been formulated at the level of the neural oscillators and their coupling, but also at the level of relative phase itself as a macroscopic, phenomenological variable. The observation of instabilities in relative timing has provided support to the notion of coordination dynamics.

Detailed Description

Coordination

That the different limbs are coordinated during locomotion seems obvious, although the phenomenon of relative coordination, in which one limb makes an extra cycle every now and then, shows that coordination requires a quantitative approach (Holst 1973). Rhythmic movements like dancing and making music, but also movements like chewing and speaking that are approximately

rhythmic, are coordinated in the sense that the relative timing of movement components remains invariant in time and, within limits, across changes of movement parameters such as speed and amplitude (Schöner 2002). Direct evidence for stable relative timing is obtained when a coordination pattern recovers from a perturbation, the lagging component catching up and the leading component falling back to reinstate the pre-perturbation pattern (Schöner and Kelso 1988). Discrete motor acts are also coordinated in the sense that their durations are aligned when the movements are performed concurrently, but not when they are performed separately (Kelso et al. 1979). The coordination of movements with external events, for example, intercepting a moving object may show the same characteristics of relative timing (Warren 2006).

To assess the convergence of coordination patterns that defines their stability, a distance measure among patterns of coordination is needed. The relative phase is such a measure. It is defined as the temporal offset of matching events in two timed movements, measured in percent of the movement time (Schöner 2002).

Neural Oscillators

A key theoretical idea for understanding coordination is that the timing of voluntary motor acts is generated from neural oscillators, whose stable limit cycles drive the effector systems (Schöner 2002). This idea is not limited to rhythmic movement. For discrete motor acts, the limit cycle may be instantiated via a bifurcation at the beginning of the movement and terminated by another bifurcation at the end of a single cycle (Schöner 1990). Perceived events may drive these bifurcations, accounting for the timing of discrete motor acts relative to the environment (Schöner 1994).

Coordination is brought about by coupling multiple such oscillators. Coupling generically induces phase locking (see entry on ► [“Multi-stability of Coupled Neuronal Oscillators”](#)). This can be visualized by looking at the rate of change of relative phase as a function of relative phase (Fig. 1). Limit cycle oscillators always have one

Coordination Dynamics, Fig. 1 The rate of change of relative phase, $d\phi/dt$, plotted against relative phase, ϕ , has a set of marginally stable fixed points when the underlying oscillators are weakly coupled (*blue solid line*) that coalesces into a single-stable fixed point for sufficiently strong coupling (*red solid line*). The *red arrows* illustrate how the

negative slope of the relative phase dynamics leads to convergence to the fixed point which accounts for recovery from perturbations and resistance to noise. The loss of stability for weak coupling leads to predictions of increased variance and relaxation time (Schöner et al. 1986)

Lyapunov exponent that is zero, which reflects that there is no resistance to perturbations that shift the oscillator along the limit cycle. In uncoupled oscillators, the dynamics of the relative phase has a line of fixed points that are marginally stable. Coupling most strongly affects the direction in phase space, in which the vector field is zero, leading generically to a stable fixed-point attractor for relative phase that represents a stable pattern of coordination.

determines the stability of the coordination pattern may be the spatial arrangement of movement components, not necessarily the anatomical nature of the components (Mechsner et al. 2001). If this were true, then perhaps cortical oscillators that control movement in space, rather than spinal oscillators directly linked to the effectors, would be the basis for coordination.

Link to Experiment

The dynamics of relative phase has been used as a direct phenomenological model of the dynamics of coordination (Schöner et al. 1986). In particular, experimental evidence for loss of stability, observed through enhanced fluctuations and slowed relaxation after perturbations, has highlighted that stability is a necessary concept for an understanding of coordination. Loss of stability is typically observed for antiphase patterns of coordination (homologous limbs alternate) when movements become faster (Schöner and Kelso 1988).

The coupled neural oscillators themselves have also been used as a level of description of coordination patterns (Haken et al. 1985; Grossberg et al. 1997) to account for the role of movement amplitude. Behavioral data suggest that what

Linear system kernel

Definition

Cross-correlation is a measure of the similarity of two signals as a function of the time lag or lead applied to one of the signals. In case the two signals are simultaneously recorded spike trains, the cross-correlation becomes a count of the number of coincidences of firing for the two spike trains as a function of the time delay between them. If one considers one spike train as the

input to a system and the other spike train as the output, then the cross-correlation function between the input and output spike trains normalized on the input autocorrelation function is equal to the impulse response of the linear part of the system. Cross-correlation can also, and in the nervous system more generally, result from common input to the two spike trains, i.e., from providing a sensory stimulus or from rhythmic or other spontaneous activity in the brain.

Detailed Description

I will use the definition of cross-correlation as standard in the field of linear systems analysis as applied to the interaction between two neurons (Marmarelis and Marmarelis 1978). I will (except when noted) assume stationarity of the spike trains. The cross-correlation function reflects the similarity of two spike trains $x(t)$ and $y(t)$, or in sampled form $x(n)$ and $y(n)$, as a function of the delay between them, expressed as a time delay τ or as the number of bins k . T is the duration of the spike trains, and N is the number of bins in the spike train. Note that the time delay can be positive and negative.

$$\begin{aligned}
 R_{xy}(\tau) &= \frac{1}{T} \int_0^T (x(t)y(t+\tau)) \\
 &\times dt \text{ or in sampled form : } R_{xy}(k) \quad (1) \\
 &= \frac{1}{N} \sum_{n=1}^N x(n)y(n+k)
 \end{aligned}$$

The cross-covariance function is obtained by subtracting the means μ_x and μ_y from the two signals (I omit the sampled form here):

$$\begin{aligned}
 C_{xy}(\tau) &= \frac{1}{T} \int_0^T ((x(t) - \mu_x) \\
 &\times (y(t+\tau) - \mu_y)) dt. \quad (2)
 \end{aligned}$$

The cross-correlation coefficient function is obtained by dividing the cross-covariance function

by the time-average variances, σ_x^2 and σ_y^2 , of the two spike trains (again the sampled form is omitted):

$$\rho_{xy}(\tau) = \frac{1}{T} \int_0^T ((x(t) - \mu_x)(y(t + \tau) - \mu_y) \times dt) / \sqrt{\sigma_x^2 \sigma_y^2}. \quad (3)$$

The expressions in the above equations are defined empirical estimates of the underlying statistics. Any deviation from a value of ± 1 for the

correlation coefficient is due to (1) nonlinearity of the system, (2) the presence of noise in the spike generation of the system, and (3) the presence of other spike train inputs to the system that contribute to the output spike train $y(t)$ but are not accounted for by the observed input spike train $x(t)$.

Representation of the Cross-Correlogram in Terms of Coincidences

In case of Poisson spike trains, the cross-correlation coefficient becomes (Eggermont 1992).

$$\rho_{xy}(\tau) = \left[R_{xy}(\tau) - \frac{N_x N_y}{N} \right] / \sqrt{\left(N_x - \frac{N_x^2}{N} \right) \left(N_y - \frac{N_y^2}{N} \right)}. \quad (4)$$

Here, N_x and N_y are the number of spikes in spike trains $x(t)$ and $y(t)$, respectively, and N is the number of bins in the total spike train duration. $\frac{N_x N_y}{N}$ is the expected number of coincidences in case of independence. For small numbers of spikes compared to the number of bins (N) in the record, i.e., low firing rates, this can be approximated by

$$\rho_{xy}(\tau) = \left[R_{xy}(\tau) - \frac{N_x N_y}{N} \right] / \sqrt{N_x N_y}. \quad (5)$$

For statistical purposes this can also be converted (holds for all firing rates) to a z-score, i.e., the number of standard deviations above the mean-corrected R , which is equal to zero:

$$z_{xy}(\tau) = \left[R_{xy}(\tau) - \frac{N_x N_y}{N} \right] / \sqrt{\frac{N_x N_y}{N}}. \quad (6)$$

Statistical significance should be set conservatively, e.g., at $z \geq 4$.

The standard normal distribution that is the basis for the interpretation of z , as the number of standard deviations between a value x and the mean μ of the distribution, is based on the z-score $z = (x - \mu) / \sigma$. For neural cross-correlograms, we generally do not have normal distributions, but we

assume that the bin filling with coincidences follows a Poisson process (the bin size should be so small that the probability of >1 coincidence is vanishingly small). For a Poisson process the standard deviation is the square root of the mean, leading to the standard deviation of the number of coincidences $\sigma_{xy} = \sqrt{\frac{N_x N_y}{N}}$.

If one wants to assess significance based on the cross-correlation coefficient, the standard deviation thereof is equal to $SD(\rho_{xy}) = \sqrt{\frac{1}{N} \left(1 - \frac{N_x N_y}{N^2} \right)}$.

For large numbers of bins in the record and relatively low firing rates, this can be approximated as $SD(\rho_{xy}) = \sqrt{\frac{1}{N}}$. So for a 900 s record length and 2 ms bin width, Δ , the $SD = 0.0015$. So taking 4 SD would make ρ_{xy} values above 0.006 significant, but one can wonder whether values close to 0.006 are relevant. For larger numbers of spikes, the SD decreases compared to this estimate.

Representations of the Cross-Correlogram in Terms of Firing Rate

The cross-correlogram is sometimes defined as a first-order conditional rate function $R_{y|x}(\tau) = R_{xy}(\tau) / \mu_x$ (where μ_x is the mean firing rate for spike

train x) that measures, for one cell y and close to any particular time t , the average instantaneous rate or the likelihood of generating a spike, conditional on an x spike τ time units away (Brillinger et al. 1976). If the trains are independent, then $R_{y|x}(\tau) = \mu_y$, where μ_y is the mean firing rate for spike train y , for all τ . If y spikes are independent of “later” x spikes (causality), then $R_{y|x}(\tau) = \mu_y$ for all $\tau < 0$. This “causality” may apparently be violated if both x and y spikes are caused with some jitter by a third, unobserved, input. Deviation of $R_{y|x}(\tau)$ from μ_y is suggestive of dependency of the y -train on what happened in the x -train τ time units earlier. For all natural spike trains, $R_{y|x}(\tau)$ will be flat and essentially equal to μ_y at large $|\tau|$ values because inevitably (with the exception for oscillatory correlograms) any influence of x on y will have vanished. Assuming a Poisson distribution, one can graph $\sqrt{R_{y|x}(\tau)}$. The variance of $\sqrt{R_{y|x}(\tau)}$ is approximately constant for all τ at a level of $(4\Delta T\mu_x)^{-1}$, so SD lines can be drawn at $\pm (4\Delta T\mu_x)^{-2}$ and become smaller in proportion to $\sqrt{T}$. This provides a good approximation if Δ is not too large and the correlation width of the process is not too large (Voigt and Young 1990).

Time-Dependent Cross-Correlation Functions

Visual inspection of the time-dependent cross-correlation function, $R_{xy}(t, \tau)$, with t as the running time in the spike trains and τ as the lag-lead time between spikes in trains x and y , shown here in an example (Fig. 1), is often the best first step in judging stationarity. $R_{xy}(t, \tau)$ without any averaging (panels a and b) represents the recurrence times (Van Stokkum et al. 1986) between the two spike trains $x(t)$ and $y(t)$ as a function of τ . Panels c and d represent the time-averaged $R_{xy}(\tau)$. The example reflects simultaneous recordings from two neurons in the auditory midbrain of the European grass frog in response to species-specific vocalizations. The left-hand and right-hand columns refer to the same data, but on the left-hand side, the correlation shown is $R_{xy}(t, \tau)$, whereas the right-hand side shows $R_{yx}(t, \tau)$, i.e., the reference unit has changed.

Vertically, the time over the first 150 s since stimulus onset, t , is shown and horizontally the lag-lead times, τ , between the x and y spikes. Different symbols indicate different order recurrence times. One observes that with the exception of the first 10 s or so, the occurrence of the recurrence times is stationary. The most important events that determine the various order cross-correlograms here (shown in part c, d) are the first-order recurrences, i.e., there are hardly any bursts (indicated by ■ and × symbols) in the y -train (a) but quite a few in the x -train (b), which had the higher firing rate. For calculation of the correlograms, we assume periodic stationarity: this means that for each stimulus presentation at intervals of P sec, the response of the neurons is statistically the same, albeit it is non-stationary in firing rate. By using ensemble averaging, i.e., in Eqs. (1, 2, and 3, the time variable is now t modulo P , and stimulus-dependent cross-correlations can be obtained.

The top correlogram is that based on only first-order recurrence times, the second one on second-order recurrence times, and the third one on third-order recurrence times; the fourth shows the all-order cross-correlogram as commonly used. All correlograms are on the same scale. The shaded correlograms are the shift predictors (see next section), calculated from the time-dependent shift correlograms shown in the bottom row that show only modest stimulus locking to the stimulus. The shape of the cross-correlogram suggests common input as the main source of correlated spike times (see later in this entry).

Pair Correlation Under Stimulus Conditions

A peak in the cross-correlogram can be the result of a neural interaction between units (“noise correlation”) but also the result of a coupling of the firings of the neurons to a stimulus (“signal correlation”) (Gawne and Richmond 1993). As we will see, the interpretation of the cross-correlogram will require both the autocorrelograms of the two units and an estimate of the correlation due to stimulus coupling. Following our earlier approach (Eggermont et al. 1983), we consider two spike

Correlation Analysis of Parallel Spike Trains,

Fig. 1 Time-dependent cross-correlation diagrams of spike trains. The different symbols used indicate the order of the spikes following the reference spike: “I” indicates the first-order recurrence time (defined in Van Stokkum et al. 1986), i.e., the first spike in the y-train following or preceding a spike in the x-train (for the left-hand column); “■” indicates the second-order recurrence time, i.e., the second spike in the y-train following or preceding a spike in the x-train; and finally “x” indicates the third-order recurrence time. (a) Simultaneous time-dependent cross-correlation diagram (no averaging involved), spikes from unit x (2,188 events) are used as triggers; (b) as (a) but now with spikes from unit y (528 events) as triggers; (c) simultaneous and

nonsimultaneous (shaded) recurrence time histograms of orders 1, 2, and 3 and cross-correlation histogram derived from (a) and (e), respectively; (d) as (c) but now derived from (b) and (f); (e) nonsimultaneous time-dependent cross-correlation diagram (defined as the correlation between the 1 s duration spike train x to stimulus presentation at t and spike train y to the next stimulus presentation at time t + 1 s), spikes from unit x are used as triggers; (f) as (e), but now with spikes from unit y as triggers. (With kind permission from Springer Science + Business Media: Biological Cybernetics, Representation of Time-Dependent Correlation and Recurrence Time Functions, volume 55, 1986, page 17–24, I. H. M. van Stokkum, P. I. M. Johannesma, and J. J. Eggermont, Fig. 6)

trains $x(t)$ and $y(t)$ of duration T and represented as a sequence of δ -functions:

$$\begin{aligned} x(t) &= \sum_{i=1}^N \delta(t - t_i) \text{ and } y(t) \\ &= \sum_{j=1}^M \delta(t - t_j). \end{aligned} \quad (7)$$

where t_i and t_j are the spike times. The cross-correlation function is given by

$$R_{xy}(\tau) = \frac{1}{T} \sum_{i=1}^N \sum_{j=1}^M \delta[\tau - (t_i - t_j)]. \quad (8)$$

For a bin width Δ and expectation $E = \mu_x \mu_y$ of $R_{xy}(\tau)$ under independence of firing of the

two spike trains, a cross-covariance histogram is defined:

$$C_{xy}(\tau, \Delta) = \frac{1}{\Delta} \int_{\tau-\Delta/2}^{\tau+\Delta/2} (R_{xy}(\sigma) - E) d\sigma. \quad (9)$$

If one presents the stimulus twice, then the resulting spike trains are $x_1(t)$ and $y_1(t)$ for the first stimulus presentation, respectively, and $x_2(t)$ and $y_2(t)$ for the second one. Presenting the stimulus twice allows us to estimate the correlation between the firing of the two spike trains based on their time locking to the stimulus. In the text I assume a long stimulus consisting of various elements. The predictor for that is to correlate spike train x for stimulus presentation 1 with spike train y for stimulus presentation 2, under the assumption that memory effects have long subsided between the two stimulus presentations. This result is called the shift predictor. For those four spike trains, one can compute ten covariance histograms (or correlograms) as shown in Table 1.

On the main diagonal two estimates, each of the units' autocovariance histograms is found. Under long-term stationary firing conditions, $C_{x_1x_1} = C_{x_2x_2}$, and one commonly uses $C_{xx} = (C_{x_1x_1} + C_{x_2x_2})/2$ as an estimator of the autocovariance function for spike train $x(t)$. For the off-diagonal elements, it is noted that, e.g., $C_{x_1y_1}(\tau) = C_{y_1x_1}(-\tau)$, therefore the table is symmetric provided that the sign of τ is adjusted. We define $C_{x_1y_1}(\tau)$ and $C_{x_2y_2}(\tau)$ as simultaneous cross-covariance histograms, and again we may use their average as an estimate for the cross-covariance function. Following our previously introduced terminology (Eggermont et al. 1983; Epping and Eggermont 1987), cross-correlations obtained under stimulus conditions will be called neural synchrony; they will be a mix of signal and

noise correlations (e.g., Gawne and Richmond 1993). Cross-correlations obtained under spontaneous firing conditions or after appropriate correction for correlation resulting from stimulus locking will be called neural correlation; they exclusively are noise correlations. During stimulation, the "total" neural synchrony consists of a component due to stimulus synchrony and one that is a result of neural connectivity, the neural correlation.

The nonsimultaneous cross-covariance histograms between spike trains $x_1(t)$ and $y_2(t)$, respectively, and $x_2(t)$ and $y_1(t)$ represent correlation between spike trains $x(t)$ and $y(t)$ as a result of stimulus coupling. These stimulus-induced correlations are known as the shift predictors. Another nonsimultaneous cross-covariance histogram is obtained by taking both spike trains for the same unit to obtain $C_{x_1x_2}$ and $C_{y_1y_2}$. These histograms represent the amount of coupling of the units to the stimulus individually and have been called "existence functions" (Aertsen et al. 1979) because any significant peak around $\tau = 0$ indicates a stimulus coupling effect and hence the existence of a stimulus-response relation. This shuffled autocorrelogram technique was rediscovered by Joris et al. (2006).

There is no model-free approach for the separation of correlations produced by direct neural interaction and those caused by stimulus coupling. Under the assumption that the effects of an external stimulus and the effects of neural connectivity to the neural synchrony are additive, Perkel et al. (1967) proposed a correction for the effects of the stimulus. Two formally identical stimulus predictors were suggested, one resulting from a cross-correlation of the two single-unit poststimulus time histograms (PSTHs), which can be used when the stimulus is periodic. One constructs the PSTHs, i.e., the cross-correlograms between stimulus onsets and spikes, $R_{Sx}(\sigma)$ and $R_{Sy}(\sigma)$, and calculates their correlation integral modulo stimulus period P (here σ is the poststimulus time):

$$R_{Scorr}(\tau) = \int_0^T R_{Sx}(\sigma) R_{Sy}(\sigma + \tau) d\sigma. \quad (10)$$

One can also calculate the cross-correlogram between one spike train and a shifted (by 1 stimulus period) version of the second spike train. This latter procedure, resulting in the shift predictor,

Correlation Analysis of Parallel Spike Trains, Table 1 Overview of possible covariance histograms for a double-unit recording with two presentations of the stimulus ensemble

	$x_1(t)$	$y_1(t)$	$x_2(t)$	$y_2(t)$
$x_1(t)$	$C_{x_1x_1}$	$C_{x_1y_1}$	$C_{x_1x_2}$	$C_{x_1y_2}$
$y_1(t)$		$C_{y_1y_1}$	$C_{x_2y_1}$	$C_{y_1y_2}$
$x_2(t)$			$C_{x_2x_2}$	$C_{x_2y_2}$
$y_2(t)$				$C_{y_2y_2}$

has been the most popular and has the advantage that it can be applied to very long stimuli (such as a set of animal vocalizations) that allow only one or a few repetitions; in such a case, calculating the PSTH would be useless. The shift predictor was assumed to represent the amount of correlation that could be attributed to the locking of the neuron's firings to the stimulus. Subtracting the shift predictor from the neural synchrony then would result in the neural correlation.

The assumption of additivity of stimulus-induced correlation and neural correlation may well be the weakest link in the chain of reasoning that leads to an interpretation of stimulus-dependent neural correlations. A strong warning against the use of the shift predictor in estimates of the neural interaction strength came from studies using realistic model neurons (Melssen and Epping 1987). Because stimulus effects and neural connectivity effects on the neural synchrony are generally nonadditive, it was concluded that the use of the shift predictor to separate stimulus and neural effects was of limited value. Yang and Shamma (1990) underlined these objections to the use of correlation methods in identifying neural connectivity and arrived at conclusions similar to those of Melssen and Epping (1987) using simulations with similar model neurons. In case of strong stimulus locking, even all synchrony can be due to stimulus correlation (Eggermont 1994). Under "adequate" stimulus conditions that evoke strongly stimulus-driven and reproducible spike trains, especially for auditory stimuli, the neural synchrony becomes identical to the expected correlation based on the shift predictor, and consequently no inference can be made about possible underlying connectivity (changes). One may avoid this overcorrection effect due to stimulus locking by applying suboptimal stimulation. Thus, a sufficient amount of "neural noise" in the record is required to allow conclusions about changes in functional neural connectivity. Thus, when stimulus-dependent neural correlations are obtained, there are a number of possibilities: the interneuronal coupling itself changes due to application of a stimulus (facilitation, depression, short-term learning), the finding is an artifact due to the selection of the wrong model, or the finding can be explained on the

basis of a pool of neurons affecting the firing behavior of the pair under study in a stimulus-dependent way.

It must be remarked that the additive model (Perkel et al. 1967) is the only one routinely used in stimulus-correction procedures (e.g., Voigt and Young 1990; Eggermont 1994). However, Srinivasan and Bernard (1976) have shown that coincidence-detecting neurons can fire at a rate proportional to the product of the rates of two input neurons, provided that their spike trains are statistically independent. The criteria determining whether the action is additive or multiplicative are the size of the excitatory postsynaptic potential (EPSP) relative to threshold and the time constant of decay for the EPSP. Specifically, EPSP values smaller than the threshold of firing and with a duration less than the average interspike interval of the individual spike trains cause the action to be multiplicative. Larger EPSP values or those with longer duration make the action additive. An alternative formulation from which this effect can be understood is that we consider a spike generator with probability of firing, g , which depends sigmoidally on the EPSP value u (Eggermont et al. 1983).

$$g(z|u) = \exp .\beta u / (1 + \exp .\beta u) \quad (11)$$

Here u is simply considered to be the linear summation of contributions u_i caused by incoming spikes z_i possibly originating from different projecting neurons. Actually $g(z|u)$ describes the well-known S-shaped curve. For relatively small u values, i.e., in the purely exponential region of the curve and temporal overlap of u_1 and u_2 , we have:

$$\begin{aligned} g(z|u_1, u_2) &= \exp .\beta(u_1 + u_2) \times / (1 + \exp .\beta(u_1 + u_2)) \\ &\approx \exp bu_1 \cdot \exp bu_2 \approx g(z|u_1) \times \cdot g(z|u_2) \end{aligned} \quad (12)$$

If the u values are large enough to be in the linear, intermediate, part of the S-curve, then after expansion of the exponential and long division:

$$g(z|u) \approx \frac{1}{2} + 1/4bu \quad (13)$$

and in case u_1 and u_2 are nonoverlapping (low spike rates), averaging over time gives.

$$g(z|u_1, u_2) \approx g(z|u_1) + g(z|u_2). \quad (14)$$

Thus, simply on basis of the size u and duration of the EPSP, the firing probability of the output neuron can be multiplicative (Eq. 13) or additive (Eq. 14) with respect to the input spike trains. In fact $u = u(t)$ and additional conditions regarding the decay time constant may enter the description.

Let us now consider that a multiplicative effect of the stimulus on spike train activity is present, e.g., by two input spike trains both depending on the stimulus and fulfilling the conditions for the EPSP but only one of these input trains is observed together with the output train. In such a case, the degree of multiplicative action is strongly dependent on the type of stimulus. Stimuli such as continuous noise that cause the input spike trains to have a relatively large time jitter, i.e., have a broad existence function, $C_{ii}(z)$, (Aertsen et al. 1979), produce results that better fit a multiplicative model than stimuli that tend to lock the spikes to a considerable degree (e.g., tone pips) as suggested by the Srinivasan and Bernard (1976) model results. Thus, also multiplicative interaction effects may be stimulus dependent. In case they are not, the application of a correction procedure based on an additive model, however, erroneously will indicate a stimulus dependence of the neural correlation (Eggermont 1994). Eggermont (2006) introduced a method to correct for these multiplicative effects, which are substantial when cortical network oscillations are present and will be discussed later on in this entry.

Practical Estimation of Stimulus Correlation

During spontaneous activity, one estimates the expected value of the cross-correlogram under the assumption of independence and subtracts this in order to obtain the neural correlation. During stimulation, the effect of a common input to both spike trains as a result of a correlation of the neuronal firing to the stimulus has to be taken into account if one wants an estimate of the true neural

correlation. If the stimulus is periodic, one can, for instance, use the shift predictor obtained by calculating the cross-correlation between spike trains $x(t)$ and $y(t + P)$, i.e., between the original x -train and the y -train shifted over one stimulus period. This method is the only one that can be used if a long stimulus sequence, e.g., a sequence of vocalizations or other natural sounds, is only repeated once, as discussed above.

As an example of this latter stimulus-correction procedure, we show recordings from the auditory midbrain to 500 ms long 30 Hz amplitude-modulated noise-burst stimulation repeated every 3 s (Fig. 2). The shift predictor is shaded and shows the 30 Hz modulation in the firing rate that obviously is stimulus locked. The triangular shape of

Correlation Analysis of Parallel Spike Trains, Fig. 2 (a) Simultaneous and nonsimultaneous (i.e., the shift predictor; shaded) cross-correlation histograms for two units recorded from the auditory midbrain in the grass frog under amplitude-modulated noise-burst stimulation of 500 ms duration. The triangular shift predictor results from the approximately rectangular stimulus envelope. A 30 Hz stimulus-locked oscillation is visible as well. (b) and (c) difference histogram shown on different time scales; W is the width of the peak at half amplitude. Bin width was 4 ms in (a) and (b) and 1 ms in (c). The number of spikes for each unit is indicated in the top right of panel A. (From Epping and Eggermont 1987)

the predictor is the result of the approximately rectangular envelope for the 500 ms long noise burst. The neural correlation consists of a narrow zero-lag centered peak approximately 5 ms in width (W) at half peak amplitude.

Rate Correlation and Event Correlation
